COMPENSATION BY DISPLACEMENT OF THE THORACIC VISCERA IN PULMONARY TUBERCULOSIS*

BY CHARLES LESTER LEONARD, A.M., M.D.,

PHILADELPHIA.

THE laws of physics render it essential that the lungs shall follow the thoracic walls and the diaphragm in their movements. This is because the lungs are distensible flaccid organs, open to the inrush of air, placed within a closed and semi-rigid bony and muscular case, which is capable of increase and decrease in its volume of muscular movements. Any alteration in the capacity of the lungs must be compensated for, or the excursion of the walls surrounding them must be decreased.

Compensation for the loss of expansion in the lungs takes place through an increase in the capacity of their normal area, or through the interposition between the visceral and parietal pleura of an area filled with air or fluid or both. These changes must take place in proportion to the volume of the lungs involved in a pathological process. They are in a measure appreciable by the ordinary methods of physical diagnosis. The changes which can be noted by inspection and mensuration are, however, less marked in ratio with the extent of the disease than those within the thorax, which produce displacements or alterations in the position of the viscera.

Tuberculous disease must be far advanced or an acute pneumo-, hydro-, or pyothorax of large volume must be present before the limitation of the thoracic movements can be noted by inspection. Marked alterations in the position of the intrathoracic viscera occur in the earlier stages of tuberculous disease, without visibly changing the excursion of the thoracic walls. These displacements occurring early in the disease have been generally overlooked. Until recently it was held that the heart and greater blood-vessels were so firmly attached by ligaments to the skeleton and diaphragm that they could not be displaced except under extreme conditions. These views were apparently upheld by the post-mortem findings.

Since they have been recognized by the roentgenologist in the living subject, it has become evident that the post-mortem changes hid the true condition. The correctness of this conclusion was shown as the result of a discussion which I had in 1909 with an internist connected with one of the largest institutions for the special study of tuberculosis. He did not believe that displacements of the viscera could occur so frequently in the earlier stages of the disease. He said that in some hundreds of post-mortems conducted at the institute they had failed to find such displacements. Some months later he told me that in the subsequent one hundred post-mortems they had found twenty-five or thirty dispacements in the less advanced cases.

These pathological variations in the position of the thoracic viscera can be clearly shown only by the rapid roentgenogram that eliminates the heart's motion. Their exact position and intrathoracic relations can only be fully appreciated by the rapid stereoroentgenogram.

The twelve cases used in illustrating the subject of this paper are taken from a series of one hundred cases studied by the rapid roentgenogram. These cases were for the most part referred for examination from the State Dispensary for Tuberculosis through the kindness of Dr. A. P. Francine, and a part of them formed the basis of a paper read by me before the British Medical Association in 1908 (*British Medical Journal*, September 12, 1908). Many, however, including some of the more interesting pathological cases, were from private practice.

In the entire series of one hundred cases 26 displacements of the heart and aorta were found with 3 cases of pneumothorax. In 17 cases the heart was displaced to the right; in 4 to the left; and in 5 a rotation took place with an upward displacement of the heart and aorta, so that the heart assumed an antero-posterior position. In 2 cases a superficial pneumothorax was found overlying the lower left lung and in one case an acute hydropneumothorax of tuberculous origin was shown.

It is practically impossible to reproduce the roentgenogram in ordinary printing with sufficient clearness to make its interpretation valuable. The 12 cases cited as illustrations of the subject of this paper have therefore been reproduced in tracings made directly from the individual Roentgen negatives. Varying types of line drawing have been used to diagrammatically represent the different stages of the pathological process.

An increased number of lines in one direction represents the line of contractile force. The tracings are accurate in detail and can be more readily appreciated by the reader. The accompanying stereoroentgenograms, if viewed through the ordinary parlor stereoscope, will show in a measure the wealth of detail which can only be fully appreciated by the study of the original negatives on the large stereoscope.

The sharp outline of the heart, seen in these plates, shows that the exposure must have been sufficiently rapid to eliminate its motion. That is, they must have been taken in a fraction of a heart's beat. The time between the stereoscopic pairs, required to shift the plates and tube, was one-half second. The total time for both exposures was, therefore, less than one second.

*Read before the College of Physicians of Philadelphia, October 4, 1911.

A review of the cases, in the entire series, shows that those cases in which no displacement of the viscera was present were early lesions, in which no fibroid change had taken place, or that the lesions were not extensive and symmetrical, or that the heart was bound down by adhesions between the pericardium and the diaphragm. The unequal elevation of the two halves of the diaphragm, Williams' sign, was present in less than one-half of all the cases, and was not present where displacements of the intrathoracic viscera had occurred. The irregularities of the diaphragm seen in the cases illustrating this paper are due to adhesions between the pulmonary and diaphragmatic pleura.

The pathological displacements of the thoracic viscera in pulmonary tuberculosis are the result of compensation for the destruction of expansive normal lung tissue by the disease.

The displacing force is the result of one or two changes or the combination of both, or as in the case of acute pneumothorax from the rupture of the lung. The consolidated lung area may undergo fibroid change and contraction, the contracting tissues drawing the heart and aorta with them, while the emphysematous lung on the opposite side assists in their displacement. That these two causes can act separately or together is shown in the illustrating cases. In some the heart and aorta are displaced in a direction entirely different from that of the pressure exerted by the emphysematous lungs or even where a marked emphysema is absent. Again a displacement is present and an extensive emphysema alone accounts for it.

In the surgical treatment of ordinary abscesses, evacuation and drainage are followed by compression, by the external dressing, to bring about coaptation of its walls and healing. Since external pressure cannot be exerted within the thorax, the same result is achieved in the natural healing abscess cavities in the lungs by the displacement of the viscera to produce compression.

In addition to the displacements which cause compression of the diseased portion of the lung, there is present in many cases an ossification of the

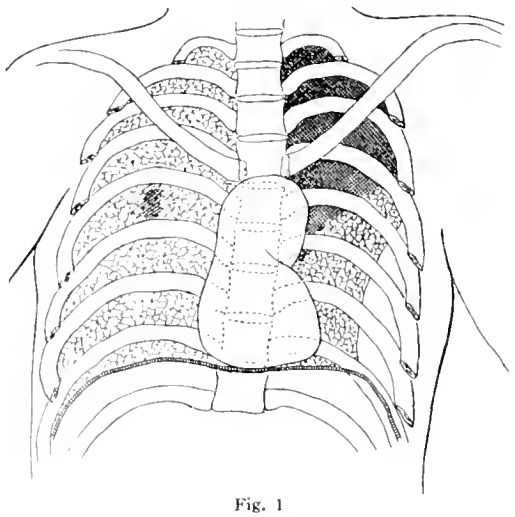

Fig. 1

costal cartilages and an approximation of the ribs over the affected area. As I have suggested in a previous paper the ossification of the cartilages may be a process of ankylosis to limit the motion of the ribs and place the parts more nearly at rest.

The compensating displacement may be divided into four groups. Displacements of the lung by superficial pneumothorax; displacements of the heart upward and into an anteroposterior position; displacements of the heart and aorta to the left; and displacements of the heart or heart and aorta to the right.

Displacements due to pneumothorax.—In both the cases of superficial pneumothorax, the physical

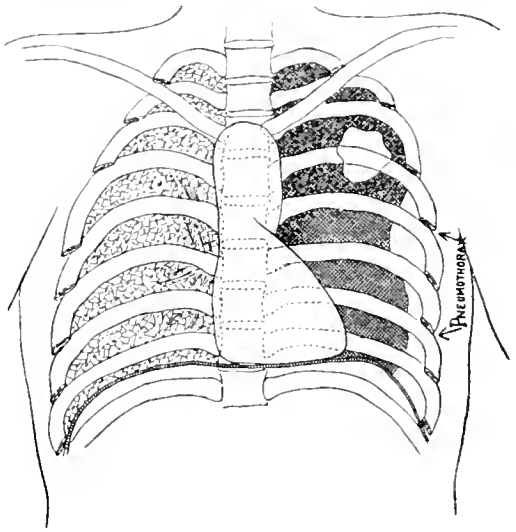

Fig. 2.

examinations which preceded the roentgen examination failed to detect them, but their presence was confirmed by subsequent physical examinations. In both cases the primary lesion was of the left upper lobe, with no involvement of the right lung. It is noteworthy that in none of the similar lesions of the entire series which involved the upper right lobe did a pneumothorax occur. The accompanying stereoroentgenogram of case I shows the lower lobe of the left lung hanging like a lace curtain within the thorax, conforming to the curve of the thoracic wall and separated from it by an area clearly devoid of all lung structure. The upper left lobe shows distinct lines of fibrosis in the infiltration, while peribronchial lymph nodes are seen in both lungs. A later stage of a similar lesion is shown in Case II, but with an entire absence of peribronchial enlarged glands. In this case the entire left lung is involved. The cavity seen in the upper lobe shows that the older lesion was there. The lower lobe is compressed, but not entirely consolidated, and is covered with a distinctly thickened pleura, which can be seen in the roentgenogram. In marked contrast to the succeeding case of acute hydropneumothorax, the heart and aorta are displaced to the left, probably entirely as the result of the compensating emphysema of the entire right lung.

The next case (III) was of particular interest, as it was an acute tuberculous hydropneumothorax. This roentgenogram was taken with the patient in the erect position, because of the fluid, which is seen as a level line just below the seventh rib. The lung is compressed upon the mediastinum and the heart and aorta are displaced to the right. This condition was readily recognized by the physical examination, but the position of the heart and aorta were not definitely determined. In this case both the lung and the heart with the aorta are displaced to the right.

Anteroposterior and upward displacements.—This displacement was found in five cases of the entire series, as illustrated in this paper by trac-

ings 4 and 5. The tuberculous lesions in all these cases were symmetrical and involved both upper lobes. The heart was not only rotated but with the aorta was drawn upward, showing that a decided force was exerted by the contracting fibrous tissue in the upper lobes. It is possible that the decreased superficial area of the heart presented

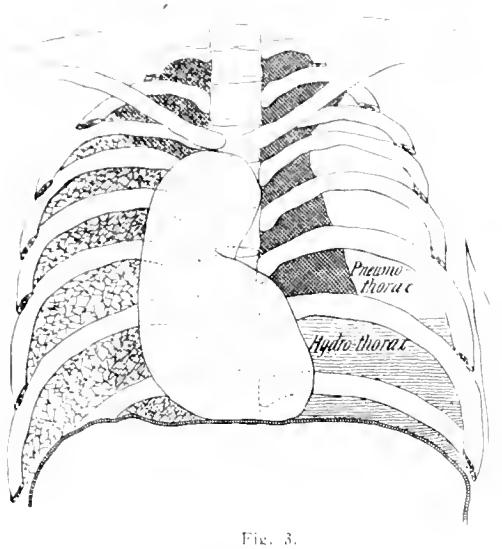

Fig. 3.

to percussion in these cases may account for an old opinion that the heart is small in tuberculous subjects. This opinion was not confirmed by the comparison between the size of the heart and the body weight of the patients in the entire series.

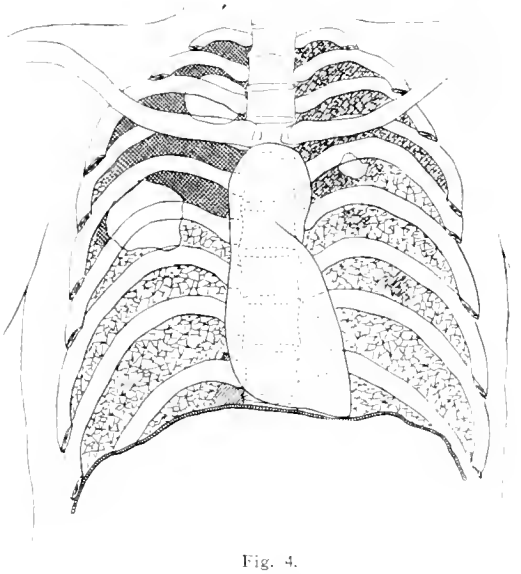

Fig. 4.

In Case IV the heart is drawn up and rotated, so that as it rests upon its apex it presents a peculiar aspect as a wide band occupying the mediastinum.

In Case V the rotation is not so complete and the band of mediastinal shadow is broader. In the stereoroentgenogram of this case it will be seen that the heart lies within a very much thickened pericardium, upon the left side particularly, which accounts for the peculiar straight line shown as its left border. The heart, however, can be distinctly seen within the pericardial shadow. The stereoscopic picture also shows very clearly a dilated bronchus forming a cavity in the right upper lobe with the surrounding infiltration and fibroid change in both upper lobes with commencing softening and cavity formation in the left upper lobe.

In the entire series of cases the displacement of the heart to the right was four times as frequent as the left in direct opposition to the opinion expressed by some authors. Of the greatest importance to the clinician is the fact, first demonstrated

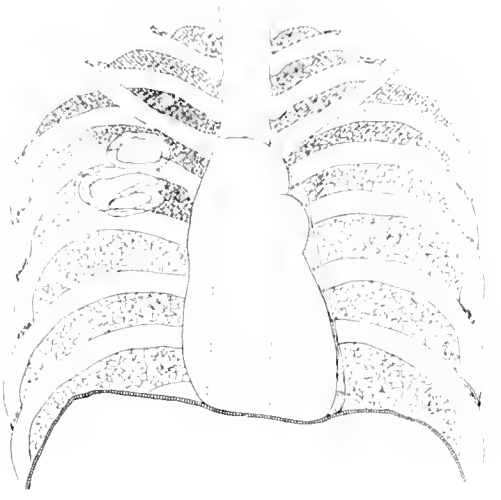

Fig. 5.

by the Roentgenologist, that the aorta is also displaced in almost every instance. It is possible in most cases to demonstrate by percussion the border of the displaced aorta that lies outside the line of the sternum, but almost impossible to show the one that lies beneath it. This fact has undoubtedly led to the diagnosis of aneurysm in many cases of displaced aorta. In only one case of the entire series was an aneurysm found. It was suspected from the symptoms presented, but could not be demonstrated by physical examination. The roentgenogram showed an aneurysm buried in a mass of tuberculous consolidation that occupied both upper lobes and a part of the lobes below them. In contrast to this is Case VIII, to be spoken of later, in which the symptoms suggesting aneurysm were found to be due to a displaced aorta.

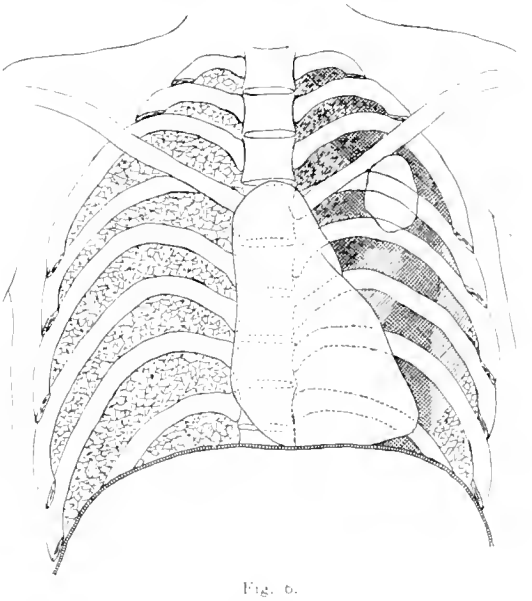

Fig. 6.

Displacements of the heart and aorta to the left.—In addition to Case II of superficial pneumothorax where the heart and aorta are displaced to the left

this group of displacements is illustrated by Case VI. Here there is an extensive involvement of the left lung. There is a cavity with surrounding consolidation and softening in the upper lobe, while consolidation and marked fibrosis have taken place in the upper portion of the lower lobe. The heart is drawn well over to the left, but the arch of the aorta is in its normal position.

Displacements of the heart and aorta to the right.—The extent to which the heart and aorta can be displaced upward and to the right, by fibrosis and contraction of a diseased area limited to the right upper lobe, is clearly illustrated in the stereoroentgenogram of Case VII. The heart and

Fig. 7

ascending aorta are drawn up so far that the arc of the arch is increased and the separation from the descending aorta is so great that one can see through the arch. The right lower lobe is evidently emphysematous and presents upon its lower surface a dome-like protrusion of the diaphragm, evidently due to a localized adhesion of the pleura. The left lung shows no compensatory emphysema, but lines of infiltration and foci of tuberculous disease can be seen scattered through it, especially on stereoscopic examination.

Fig. 8

The displacement of the heart and aorta in Case VIII gave rise to symptoms which led the laryngologist to suspect the presence of an aneurysm in an evidently tuberculous subject. In addition to a paralysis of the vocal cord the case presented other very interesting features, and has been reported in detail by Dr. E. L. Van Zandt before the Laryngological Section of the College, by whom it was referred for Roentgen examination. The Roentgen plates showed that no aneurysm was present, but that the heart and aorta had been displaced far to the right. The tuberculous lesion was confined chiefly to the right upper and middle lobes, where consolidation, fibrosis and cavity formation had taken place.

The multiple lesions of a rapid tuberculous process, as well as a moderate displacement of the heart and aorta to the right, are shown in Case IX.

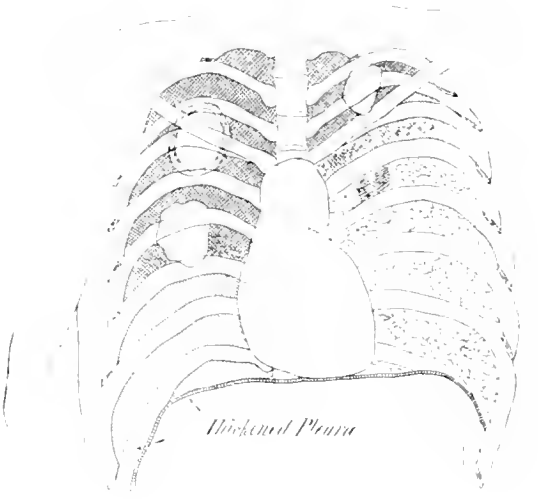

Fig. 9.

Here we have infiltration, consolidation, fibrosis, an old walled cavity, the breaking down of tissue to form a cavity, a cavity in the left upper lobe without a thickened wall, and an area of the lower right lobe covered by thickened pleura.

The remaining cases are illustrations of displacements to the right of the heart and aorta, and are the types of cases readily recognized and termed dextrocardia. Displacement of the aorta to the

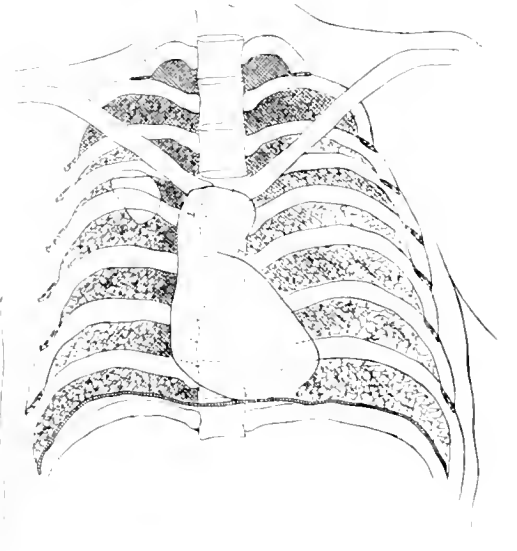

Fig. 10.

right is also present, but had not been determined by the physical examination, while Case XII is the

only case in the entire series in which displacement of the aorta did not occur with the displacement of the heart.

The moderate displacement of the heart and aorta to the right in Case X can be accounted for by the adhesion of the pericardium to the diaphragm and the general fibrosis which has accompanied the miliary tuberculosis.

The small masses of miliary tubercle are seen distinctly, especially in the original negative and the lantern slide, scattered throughout both lungs accompanied by bands of infiltration. The upper right lobe is consolidated, with fibroid change and cavity formation.

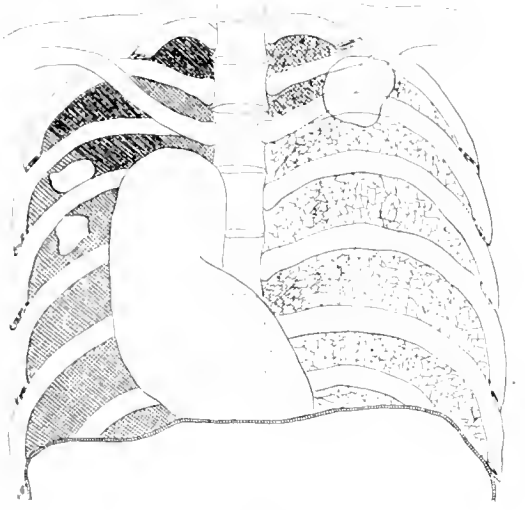

Fig. 11.

The wide displacement due to consolidation of the entire right lung with fibroid contraction and emphysema of the left lung is illustrated by Case XI. The original seat of the disease is shown by the advanced fibroid change in the right apex and the cavity formation. The heart and aorta are drawn far over to the right and slightly upward. The spread of the disease to the left lung is seen in infiltration and early cavity formation in the left upper lobe.

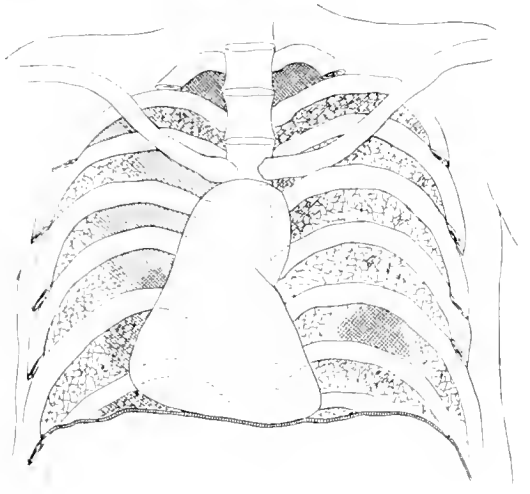

Fig. 12.

Another illustration of dextracardia with advanced fibroid change is shown in Case XII. The apex of the heart is displaced nearly to the median line. In this case, however, we find the arch of the aorta in its normal position. This absence of displacement is probably due to the general fibrosis which is evident throughout both lungs and the absence of consolidation and extensive fibrosis of the right upper lobe. This is the only case where the aorta was not displaced and also the only one of displacement to the right in which the right upper lobe was not extensively involved by the disease.

In all the cases illustrating this paper and in the entire series from which they are taken, the clinical findings have been compared with the röntgen diagnosis and the points brought out alone by the röntgen examination have been subsequently confirmed by a physical examination.

The röntgen method of examination has been shown to add to the knowledge obtained by other methods of physical diagnosis, by detecting superficial areas of pneumothorax, by showing that the aorta is generally displaced with the heart and by making evident the effect of fibroid change in displacing the viscera through its contraction. In addition it is a valuable mechanical method of observing and recording the changes and displacements produced within the thorax by tuberculous lesions of the lungs. It also assists in the understanding of the processes of repair which take place in the closing and healing of old cavities, while it forms a permanent record for comparison with that obtained in later examination, thus showing the progress of the disease or of the process of repair.

It is self-evident that röntgenoscopic examinations of the thorax and lungs, that is, the visual examination by means of the röntgen rays and the fluoroscope, cannot afford accurate permanent data such as are secured by the rapid röntgenogram and particularly the stereoscopic röntgenogram. There can be no doubt that viewing with the fluoroscope is a cheaper method and that is less accurate since it gives data that are only visible to the eye of one observer. It possibly affords an advantage in viewing the movements of the diaphragm, but it cannot eliminate the effect of motion produced by the heart's beat and does not show the minute detail essential to a careful diagnosis. An examination sufficiently long to enable the observer to gain any valuable information must necessarily expose the patient to the rays for a far greater period then the second or two required for the rapid stereoröntgenogram.

The series of cases illustrating this paper in tracings, stereoröntgenograms and lantern slides show the contribution which röntgenology has made to the knowledge of the pathological displacements of the thoracic viscera produced by the lesions of pulmonary tuberculosis.

112 South Twentieth Street.

PEDIATRIC MEMORANDA.

MYELOCYSTOCELE. SPINA BIFIDA OCCULTA.

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK.

Myelocystocele.—The child was only three weeks old when the illustrations (See Figs. 1 and 2) were obtained. It weighed nine pounds, was quite comely and unusually bright and active for its age. It was the first child of strong Irish parents, who apparently were free from syphilis, tuberculosis, or other constitutional taint. They brought the baby to Dr. J. Lipman for treatment and he kindly referred it to my hospital service. On examination I found a protrusion, about 2 inches in diameter, with a broad base situated at the lower lumbar region of the vertebral column (see Fig. 1). The

covering skin was greatly distended but normal in color. The tumor was not translucent and on palpation proved to consist of a semisolid mass. On firm compression it could be considerably reduced in size, but its manipulation gave rise to great

Fig. 1.—Myelocystocele.

annoyance to the patient, apparently by upward pressure upon the brain. On further inspection I noted pronounced, funnel-shaped eversion of the rectum, owing to paralysis of the levator and sphincter ani; rectangular curving of the femurs at the hips; right talipes varus, and cohesion of the fingers and toes (see Fig. 2). The motor and sensory functions of the lower extremities seemed but slightly disturbed. This last observation as well as the absence of bluish discoloration of the skin aided in the exclusion of myelocele, and it differed from meningocele by being neither ped-

Fig. 2.—Same case as in Fig. 1, showing the clubfoot and syndactylism.

unculated nor translucent. The case was transferred to Dr. E. W. Peterson for operation, but the doctor suggested waiting a few months longer—presumably to give the infant the choice of a natural death.

Spina Bifida Occulta.—The seven year-old boy was admitted to the hospital for protracted cystitis. According to the parents the child has always suffered from *Enuresis diurna et nocturna* and irritable bladder. He was seen by several physicians and underwent different methods of treatment without noticeable improvement. While in the hospital he complained of strangury and rectal tenesmus, and the urine contained pus and blood corpuscles, bladder epithelium, and numerous bacteria. On a milk diet, bladder irrigation (nitrate of silver 1 to 2000), and the administration of extract of hyoscyamus (1/12 grain), and hexamethylenamine (4 grains) every four hours, the painful symptoms abated after a few days, but the enuresis improved but little. Careful rectal digital examination failed to reveal a vesical cal-

Fig. 3.—Spina bifida occulta.

culus or tumefaction. The case remained a diagnostic enigma for several weeks when one day I happened to see the boy bending over a bed chamber trying hard to expel a few drops of urine. To my great surprise I noted a small prominence at the sacrolumbar region (see Fig. 3). When he stood erect the swelling, as it were, flattened and was barely noticeable, hence the reason why it had escaped our observation. On further examination I found that a small spinal cleft was hidden under a mass of fat. We also observed that his walk was somewhat dragging and awkward. With these manifestations in view, it was quite clear that we were dealing with a case of spina bifida occulta. Hypertrichosis, which is usually associated with this form of spina bifida, was absent. This experience has taught me ever to examine a patient with recalcitrant enuresis or cystitis for spina bifida. In doubtful cases the diagnosis can often be settled by means of the *x*-ray. Judging by the gradual appearance of graver symptoms, this seemed to me an ideal case for operative interference, *i.e.* separation of the adhering strands of the cord from the covering skin. If left alone the symptoms gradually grow worse, since owing to the normal ascent of the cord with increasing age of the patient there is a corresponding increase in the spinal tension. The parents, however, did not consent to an operation.

127 West Eighty-seventh Street.

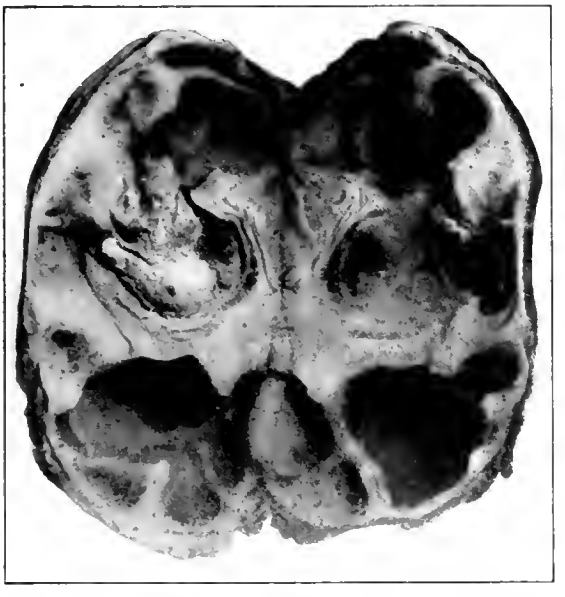
ACIDOSIS FOLLOWING NEPHRECTOMY.

By J. BENTLEY SQUIER, M.D.,

NEW YORK,

PROFESSOR OF GENITOURINARY SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Lewis Beesley (*British Medical Journal*, 1909, p. 1142) calls attention to the fact that the clinical similarity of symptoms described as occurring in so-called acid intoxication and delayed chloroform poisoning points to similar metabolic disturbance in the organism, one of the ultimate products of which is acetone. A grave form of delayed acetone excretion may occur after operation, and is shown by a sudden fall in the acetone curve, instead of the gradual ascent. That less is passed than is expected, breath smelling of acetone, points to the fact that a condition has arisen which hinders the excretion of acetone. The frequency of this condition after chloroform as compared with ether suggests the possibility that there is some additional factor present in chloroform, which, besides producing acetonuria, acts upon other organs, rendering them incapable of reacting to the strain of acetone excretion.



Our knowledge of the true cause of acidosis following operation is not complete and various hypotheses have been offered. Guthrie, discussing cases that died from acidosis following anesthesia, laid stress on the fact that autopsy showed the liver to be markedly fatty, and argued that this fatty condition could hardly have resulted from the comparatively short chloroformization. He advanced the view that a fatty liver was probably present beforehand and acted as a predisposing factor. Bracker, Stone, and Low of Boston state that "one of the conditions under which an increase in acetone excretion occurs is phosphorus poisoning, the acetone excretion taking place as the result of the destruction of fat tissue. They believe the toxic symptoms are due to the fatty antecedents of acetone rather than to acetone itself." Waldvogel attempted to prove that acidosis was chiefly referable to the withdrawal of food in preparation for the anesthetic and to the subsequent vomiting. In several cases he was able to show that the acetonuria did not appear if the patient was etherized on a full stomach and did not vomit after recovery. Yet, since children of from six to nine years whom he allowed to fast for seven hours failed to show increased acetonuria, and since the influence of carbohydrate in relieving the acidosis was much slower than in simple starvation, Waldvogel was forced to conclude that a direct toxic action of the anesthetic was an important factor in producing the acidosis. Experimental confirmation of the last cited opinion has recently been published by Cragin and Hull. It was shown by them that relatively short anesthesia with chloroform might lead to very extensive lesions of the liver with serious or even fatal outcome.

At all events, acetone is present in the urine in many different conditions, and is much more common than is generally supposed. There is so little in the healthy urine that it cannot be detected by color tests, but by a quantitative analysis a trace is usually found. The condition is more marked in women than in men, and most marked in children. Some writers claim that the length or character of the narcosis does not influence its appearance.

A patient, who succumbed with symptoms of delayed acetone excretion following nephrectomy, presented the following history: A woman, sixty years of age, consulted me on October 11, 1910; twelve years before a large abdominal tumor had been removed, of the nature of which she was uncertain, but probably it was a fibroid of the uterus. After recovery from the operation, she was in good health until a year ago, when she developed backache and began to lose weight. At the same time pus was discovered in the urine. She was advised to go to Wildungen for a course of treatment, which she did. During the year she lost thirty pounds in weight. Cystoscopy showed a hyperemic bladder except for a mild degree of cystitis. Both ureteral orifices appeared normal. Urine drawn from the left kidney was loaded with pus, with a low specific gravity. Urine from the right kidney showed absence of pus, a trace of albumin, and a few hyalin casts. The left kidney was easily palpated and seemed about twice the normal size. Radiographic examination showed the presence of large and small calculi in the left kidney. The heart was dilated with a blowing systolic murmur heard over the apex. The lungs were emphysematous and the liver percussed small.

Operation was decided upon, and on October 15 left nephrectomy was performed. The anesthesia was started with ether, but as considerable pulmonary irritation was produced chloroform was substituted. The kidney was found to be composed of a number of pus sacs containing large and small calculi (See cut). The patient was under anesthesia twenty-five minutes and recovered from the operation, with the exception of some watery emesis, without incident. In the first twenty-four hours twelve ounces of urine were voided. She continued in good condition for four days. The average amount of urine excreted in twenty-four hours was twenty-five ounces. The urine analysis at this time showed an acid reaction, a specific gravity of 1010, a trace of albumin, hyalin casts and some pus cells. The temperature ran at 100° F., and fell to normal by the fourth day. On the fifth day a heavy sweet odor of the breath was noticeable and she developed great excitement. The blood pressure rose from 160 to 220, and the pulse beat from 80 to 100. The temperature remained normal. On the seventh day traces of acetone were first found in the urine. The patient became progressively worse and went from excitement to delirium. She died on the twelfth day after opera-

tion. The temperature had been normal for eight days. The pulse ranged from 90 to 100. The daily excretion of urine averaged 30 ounces. Examination of urine the day before death showed the following: Reaction, acid; sediment, moderate; albumin, trace; bile pigment, negative; urea, 1.058 per cent.; indican, excess; color, amber; odor, not offensive; specific gravity, 1,012 at 150° C.; sugar, negative; acetone, traces; chlorides, 0.5 per cent. Microscopic examination: Blood, none; pus, some cells; mucus, small amount; casts, some hyalin; bacteria, slight bacteriuria; epithelium, some bladder cells; crystals, none. The treatment besides symptomatic was the administration of large doses of sodium bicarbonate by mouth and rectum.

It was surprising that the evidence in the urine of an acidosis was not more marked, in view of the clinical symptoms. Nevertheless, it is a fact that the evidences in the urine are not necessarily in proportion to the symptons. It works both ways; severe symptoms, little in the urine (always some); slight symptoms, much in the urine. These are, however, exceptions. After the patient's death, her family informed me that following the operation for removal of the uterine tumor, which the patient had undergone twelve years before, she had developed a condition of coma. This condition lasted for a week before the patient began to improve. Whether, in this case, the termination was due to the acidosis as an exhibition of delayed chloroform poisoning, a bacterial autoinfection, or a manifestation of the so-called status lymphaticus is a matter of conjecture. The patient before operation had somewhat the appearance of one suffering from myxedema. The presence of the acetone bodies in the blood or urine as actually being the cause of the symptoms of delayed chloroform poisoning or merely as an evidence of grave changes either in the function or structure of the cells of the liver or other organs is by no means finally settled. Prolonged acidosis without symptoms is not unknown in diabetes and neutralization of the acids by infusion of massive doses of alkalies does not always produce amelioration of the symptoms designated for convenience as acidosis.

MARTINUS VAN HILLE

AND

HIS TREATMENT OF GONORRHEA AND SYPHILIS IN THE SEVENTEENTH CENTURY.

By JOHN BETHUNE STEIN, M.D.,

NEW YORK.

Martinus Van Hille was born at Antwerp in 1633. He lived when Belgium, without a national dynasty, was poorly or badly governed by Spain and became the object of controversy by her ambitious neighbors and the field of battle for almost all the wars of Europe during the seventeenth and eighteenth centuries. Study of all kinds, commerce, industry, letters, science, and art felt the baneful influence of the political conditions of this period.

We cannot procure any information of the early life of Van Hille. He studied surgery in Antwerp and later went to Holland to perfect his knowledge in this branch of medicine, and in 1665 we find him among the military surgeons in the service of the United Netherlands.

On June 17, 1665, in the memorable sea battle between Holland and England, when the Dutch "swept the seas," Van Hille was surgeon on board the ship commanded by Admiral Tromp, where he treated the wounded.

Van Hille, in speaking of a case of gangrene which demanded the amputation of a limb, expresses himself as follows (page 145 in his Manual of Surgery, "Tooneel der Chirurgie"): "It is better that the limb be amputated at once before the patient loses his strength and is subjected to an incurable gangrene. This I have witnessed with great success on the ship of my master, Tromp, on June 13, 1665, in the battle against the English when I saved my patient, a sailor, who had the bones of the carpus and metacarpus on the left hand so badly injured by the flying splinters from the ship, that there was no hope of restoring it, and that in a short time in spite of all the necessary cares which were given him would have become gangrenous." After obtaining sufficient experience Van Hille resigned his position of surgeon in Holland and returned to his own country. There

MARTINUS VAN HILLE—1633-1706.

Licentiate in Medicine from the University of Louvain, Professor of Surgery in the School of Surgery at Antwerp, Military Surgeon in the Service of the United Netherlands, and Surgeon on Board Admiral Tromp's Flag-Ship During the Holland-English War.

were few good operators at this time, and the fame of the surgeon of Admiral Tromp, which preceded him to Antwerp, combined with the proofs of the knowledge which he had acquired in Holland soon obtained for him the confidence of the people.

In the dedication of Van Hille's work on surgery he states there existed at Antwerp a college of medicine and a college of surgery; that the latter was founded about the middle of the sixteenth century and was under the direction of a dean (opperdeken) a vice-dean (onderdeken) and two of the elders (oudermans) of the corporation of surgeons.

Among other privileges accorded the surgeons at Antwerp was the right to name, directly, the professor who should instruct the students.*

As the talents of Van Hille were generally appreciated, the corporation of surgeons at Antwerp

*See "Notice sur David von Mauden, docteur en Médecine," by C. Broeckx, Anvers, 1850, p. 23.

offered him the chair of surgery in the Collegium Chirurgicum, which he accepted and filled for ten years. He always held the attention of his auditors by his devotion to his work, his lucid method of imparting the anatomical and surgical knowledge of his time, and the fact that he forced himself to keep his teachings on a level with the discovered facts in the different parts of the world.

Although Van Hille was considered the best operator in his city and had acquired the high esteem of all classes, the title of surgeon did not suffice him and he resolved to become a graduate in medicine. To that end he began the study of medicine and presented himself to the examiners of the University of Louvain. This was not so easy, especially for one who had never studied the humanities; nevertheless, by virtue of his zeal for study and his fund of knowledge, he graduated in 1678 and was made, the same year, a member of the College of Medicine at Antwerp. In the book of receipts of the College of Medicine at Antwerp in 1678 we read that he paid 36 florins (Brabant) for his admission and 4 florins for the privilege of a seat. (Broeckx.)

Twice in 1682 and again in 1694 Van Hille was elected syndic of the medical corporation at Antwerp, and in this position defended with much zeal the dignities and rights of his profession against charlatanism.

The records of the Collegicum Medicum show that persons without diplomas were practising the art of healing. These were brought before the magistrates and convicted under the law promulgated by Charles V and the county authorities. The placard of Charles V (October 8, 1540) and the ordinances of the county authorities prohibited under severe penalties the practice of medicine by persons who had not received a diploma.

After having filled with distinction the several position to which his colleagues had elected him, Van Hille sought to settle "the debt which every physician seems to contract on entering the career of medicine; to leave behind him a useful and known result of his experiences and his efforts for the progress of the science." That he did in his later years. In 1700, after forty years of practice, he presented the results of his extensive clinical experience in a work entitled Tooneel de Chirurgie* (Manual of Surgery) which consisted of questions and answers for the use of his pupils.

His manual of surgery is divided into two parts. The first part treats of the divisions of surgery, the surgical antaomy of his time, the organs and their functions (digestion, circulation, respiration, nutrition), and general pathology. The second part is devoted to practical surgery; to tumors in general and particular, with their diagnosis, prognosis, symptoms, and treatment; to suppuration; to an extensive consideration of the different kinds of gangrene, gangrene through freezing, lack of nutrition, and that which is due to the absorption of a "malignant humor." After indicating the curative measures for a gangrenous limb, and the manner of applying them, he tells under what conditions and how such a limb should be amputated.

Erysipelas, edemas, scirrhous tumors, and cancer are considered in detail. All that the author taught on hernia, its causes and treatment, conformed to the knowledge of the epoch. His work shows that he made a close study of wounds in general, and of the head, chest, abdomen, and nerves in particular. The sequelæ of wounds of the head are clearly described by him.

The nature and treatment of gunshot wounds, naturally, find a place in his work. He next takes up the study of burns and "poisoned" wounds, ulcers (phagedenic and those with indurated borders), fistulæ (lacrymal, pectoral, and anal), and closes with a description of fractures and dislocations.

As syphilis was making great ravages at this time Van Hille "thought he would render a service to science by adding a short treatise on syphilis to his manual of surgery."

He reviewed the symptoms and treatment of gonorrhea and its complications, recommended the use of emollients internally as well as emollient injections during the early stages of the disease, and advised using oil of turpentine and astringent injections only when the acute symptoms had disappeared. He altogether disapproved of the use of astringent injections at the commencement of the disease, and prescribed a suspensory bandage to prevent testicular complications. His treatment of epidydimitis and orchitis is very rational. For stricture of the urethra he used bougies, alum, and zinc sulphate.

For chancres he employed mercury both internally and externally as well as decoctions of sarsaparilla; decoctions which strongly resembled "le rob" which was widely used in the early part of the last century by charlatans in Paris as "the only antidote for syphilis and many other ills." After the consideration of buboes, phimosis, and paraphimosis he took up the treatment of syphilis.

He divided syphilis into two periods, recent and confirmed, which correspond to our divisions of primary, secondary, and tertiary periods. He discussed the different methods of treatment as proposed by A. Paré, C. Battus, Fernel, and those who were his contemporaries.

As syphilographers to-day are not in accord as to what is the best form of treatment of syphilis, it may be of interest to know what Van Hille employed about the middle of the seventeenth century. The patient was first bled and purged, ordered to stay in a "hot atmosphere" and given sudorifics. This was followed by inunctions of mercury and hydrargyrum oxidum rubrum was given internally up to the point of salivation. He took care to have an interval of time elapse between both the rubbings and the administration of the internal medication "in order to master this phenomenon (salivation) at times so troublesome." At this time, as well as later, there were those who opposed the use of mercury in syphilis and attributed all kinds of lesions to the administration of it. "It is that they do not know how to employ it," says Van Hille. "Mercury is the true antidote for syphilis and salivation is necessary in order to expel the venereal virus from the body."* Van Hille also found that the salivation was accompanied at times by severe lesions which he describes at length and for which he recommends treatment.

Van Hille's Manual of Surgery shows him to have been a practitioner, well instructed, with good judgment, abreast of the knowledge of his time and possessing the talent to demonstrate his doctrines with great clearness. If he did not make any great discoveries, he nevertheless gave his contemporaries much which was of profit to them in

*See "Considerations sur le péritonite," par Van den Zande, Anvers, 1821, p. 8.

*P. 215, "Tooneel der Chirurgie."

their practice; and his treatise on syphilis is the fruit of many years of practice as a military surgeon, during which time, he had the opportunity to observe a large number of syphilitic affections. His work was not only well received by his pupils and colleagues at Antwerp, but many of the latter addressed pieces of verse to his honor, one of which, written by Casimer Vilella, his successor to the chair of surgery in the Collegium Chirurgicum, is printed on the first page of the "Tooneel der Chirurgie." The second edition of Van Hille's work appeared in 1726, twenty years after his death.

POST-OPERATIVE TREATMENT OF GENERAL SUPPURATIVE PERITONITIS.*

By ASPINWALL JUDD, M.D.,

NEW YORK,

ADJUNCT PROFESSOR OF SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In probably no class of cases with which we come in contact as surgeons is after-treatment so important a factor as in general suppurative peritonitis. Various methods of treatment of this condition at the time of operation have been exploited, the exponents of each being emphatic in their advocacy of their own particular method and each condemning with great severity all methods but their own. In only one point of technique are they all agreed—the necessity of the most rapid operation possible compatible with any sort of thoroughness. Personally I am firmly of the opinion that the flushing of the peritoneal cavity with various solutions, the making of multiple incisions except in rare instances, and the handling of the intestines is to be avoided wherever possible. As is well known, the lymphatic supply of the upper portion of the abdomen, and especially in the diaphragmatic region, is particularly abundant, and it seems to me that every effort should be made to prevent driving bacteria into this locality, where the absorption of toxins is so rapid as to produce an overwhelming effect upon the system. The wiping off of the peritoneal surfaces is also contraindicated, as, in denuding the membrane of its outer covering, we promote the rapid formation of adhesions with the locking in of pockets of septic material, as well as promoting its more rapid absorption. According to Murphy and others, it is extremely questionable whether we ever secure thorough drainage from the peritoneal cavity, possibly excluding its pelvic portion, for more than twelve hours.

In the list of thirty-eight patients, extending over a considerable period of time mostly in my own service, most of the case histories of which are appended, I have followed out the general method of fairly wide single incision, if by this incision I was able to reach the seat of infection, evacuation of the septic contents by gentle sponging, and the repair of the viscus as rapidly as possible. In the case of the appendix where by prolonging my search I felt I was endangering the life of my patient I have terminated my efforts in this direction, merely placing a large drain at the site of the lesion, as has been so long recommended by Morris, Tate and others, and have returned my patient to bed at the earliest possible moment. In my hands the large, loose cigarette drain made of gauze covered by gutta percha tissue, frequently fenestrated, or in some cases the use of a large rubber or glass tube, has given me most satisfaction. Twenty minutes is a long time to keep one of these patients upon the table, and the more this can be shortened the better is our chance of a speedy recovery. Many of these patients were practically in extremis at the time of operation. In many of these cases I have administered an infusion of from 1,000 to 1,400 c.c. of normal saline solution, in which from 1 to 2 drachms of adrenalin solution has been added at the time of operation or immediately succeeding it. By this means alone I feel that a considerable proportion have been tided over the first twenty-four hours succeeding operation. Cultures taken from three of my patients showed pneumococcus bacilli. In over 50 per cent. the cultures were either streptococcus or streptococcus plus colon bacillus. In the remainder the colon bacillus was predominant.

After-Treatment.—Immediately upon being returned to bed the patients are placed in an exaggerated Fowler's position, that is, with the head of the bed very much raised upon high shock blocks. If the patient's condition is desperate intravenous infusion is administered, as stated above. The intravenous infusion has proved very much more effectual in my hands than any other method, is no more painful, is more rapidly and thoroughly efficient, and no more difficult to administer. As light a dressing as possible is applied, three or four layers of sterile gauze being all that is required. This dressing is kept moist with saline solution and changed as often as may be required, sometimes every three hours. An ice coil of large size is applied and kept going continuously. Ice bags do not answer our purpose. They are weighty, require frequent renewal, fail to keep an even temperature and are at times much too cold and at others ineffectual. Murphy's drip, a continuous rectal irrigation, is at once started. In some cases my patients have absorbed as much as 140 ounces of normal saline in twenty-four hours by this method. A minority of patients are unable to retain the fluid, but will absorb 4 ounces of saline to which may be added 1 ounce of whiskey every three hours. We often find that an enema of this size, given every three hours, will be completely taken up without effort, where a larger enema of 8 ounces, administered every four or five hours, will be rejected. My earlier cases were all treated by this bethod. Absolutely nothing is given by mouth. The lips and tongue are frequently moistened with water applied by a swab, but not one drop is allowed to be swallowed. This treatment is persevered with for a variable length of time, from forty-eight hours in the milder cases to thirteen days in one case reported. To prevent desiccation or in case of shock, a second or even a third intravenous infusion of 1,000 c.c. normal saline solution is administered. I have given three infusions within four days with no evil results. By this method, plus the Murphy irrigation or Fowler enemata, the craving for water is very greatly reduced. The tongue does not become dry nor the tissues desiccated. No opium or sedatives of any

*Read before the Academy of Medicine, October, 1911.

kind are administered as they tend to diminish excretion and prevent secretion. Strychnine and other heart stimulants are given as required strychnine, as a routine, 1-30 of a grain four times a day, increased as may be necessary. In very few cases have I found it necessary to resort to any of the more difusable heart stimulants, such as camphor and oil, ether, musk, etc. By this means of treatment, *i.e.* the ice coil and nothing by mouth, peristalsis is absolutely inhibited, and, as a result, pain is completely absent and distension rarely occurs. Only a very few of my patients have complained of the slightest discomfort outside a mild craving for water. Hunger is completely abolished.

A blood count is made upon the second day as well as before operation. It is known that a high leucocyte count is a very favorable prognostic sign. Each twenty-four hours my drains are started, pulled out from ½ to 1 inch and cut off. This, in conjunction with the moist, wet dressing, insures good capillary action and copious drainage. At the end of forty-eight hours, if my patient is doing well, I replace the large by short shock blocks, reduce the Murphy irrigation to twelve hours in twenty-four, or, in the case of Fowler's enemata, cut them out during the night and administer tentatively a medicine dropper full (containing 15 to 20 minims of water), alternating with peptonoids or panopeptone every fifteen minutes. This is done as much for the psychic effect upon the patient in making him think that he is getting something by mouth as for the effect of the fluid itself. This fluid is absorbed in the esophagus and the stomach and produces no peristalsis. In twenty-four hours more in the very favorable cases the ice coil is used each alternate four hours. The quantity of fluid given by mouth is doubled or trebled, the quantity used depending upon its failure to produce peristalsis. If our symptoms still remain favorable the fluids given the patient thereafter are rapidly increased in quantity until a normal amount is allowed. As soon as a normal quantity of fluid is given the Fowler's enemas are discontinued. The bowels in all cases are moved by enemata only up to the sixth day and in severe cases nothing is done beyond cleaning the rectum for the better administration of saline enemata. In one of my fatal cases the failure to follow out this procedure resulted in rapid toxemia and death on the seventh day, after my patient had made an uninterrupted convalescence for five days.

In those cases in which the appendix was not found or in which the hole in the intestine was not repaired a fecal fistula usually made its appearance from the third to the sixth day. This I have found to be a matter of no consequence. Ninety per cent. of these fistulæ close of their own accord under appropriate treatment without further operative interference, thorough irrigation with permanganate of potassium solution, with a high irrigator containing from 2 to 4 quarts, twice a day, the insertion merely of a soft rubber tube down to the bottom of the fistula, this tube being reduced in caliber and in length as the fistula closes, being quite sufficient as a means of cure in most of the cases.

It has been the common experience of most surgeons that our cases of peritonitis under almost any method of treatment go on fairly well for from forty-eight hours to three days, and then suddenly shoot a temperature of 106 to 107, get an increasingly rapid and finally imperceptible pulse, and finally die of extreme toxemia. Where, in spite of all precaution, my patients have suddenly started upon this course, I have found that an intravenous infusion would almost invariably bring the temperature down to somewhere near normal within from six to twelve hours with a corresponding improvement of pulse. In a few cases I have found it necessary to repeat this procedure on the fourth or fifth day. As will be seen from the case histories, in few of these cases has the post-operative temperature been very high at any time with the exception already mentioned, rarely going above 103. My endeavor in the treatment of this condition has been to absolutely limit peristalsis, with a consequent absence of pain, and to prevent not only the absorption of septic material, but to produce, according to Murphy, an exosmosis into the peritoneal cavity with a subsequent washing out of this septic material. The inhibition of pain and peristalsis by means of opium and other sedatives, while it unquestionably adds to the comfort of the patient, also produces inhibition of secretions and excretions and is to be avoided accordingly. The former bete noire to the use of prolonged cold upon the abdomen was the fear of a paralysis of our vasomotors with a consequent dilatation of our blood vessels. In the use of the ice coil I have never found this to be true, having used it continuously for as long as eight days and at intervals thereafter in the same patient for seven days more. The peritoneal cavity is never frozen, but an even cool temperature is maintained sufficient to prevent peristalsis and absorption.

Where it is necessary to deprive the patient of food by mouth for longer than four days in a well nourished individual, or longer than forty-eight hours in a fragile person, I have alternated nutrient enemata with my Fowler's enemata or rather have administered from two to four nutrient enemata each day. Where this is done it is essential that we wash out the rectum once a day fairly thoroughly. As I have already stated, cathartics by mouth are absolutely contraindicated in all cases during the first week and even longer unless we are perfectly positive that we have seen the end of our infection. In two or three cases where post-operative ileus has developed with great distension as a last resort I have administered through a stomach tube from 3 to 4 minims of oleum tighli suspended in 1 ounce of castor oil, this after washing the stomach clean. In one case this procedure was repeated three times within thirty-six hours, with an aggregate dose of oleum tighli of 8 minims. The result in each case has been a thorough evacuation of the bowels. I realize that in adopting this measure I have stultified myself, in that I have promoted extreme peristalsis with consequent considerable absorption of toxic material, but this measure has been resorted to only in those cases in which death was inevitable without some radical procedure, and after this measure has proved effectual I have immediately gone back to my routine treatment. I have omitted to mention that where the stomach became distended it has been my custom to wash it out as often as might be required. This can be done without starting up peristalsis.

In two of my cases I attribute the final favorable result to a spontaneous opening up of the intestine on the third to the sixth day following operation. This has led me to attempt an enterostomy or colostomy for the relief of desperate symptoms in some other cases, but so far I have been less successful in preventing a fatal issue than have others

who have reported similar cases. The most unfavorable class of cases with which I have had to deal have been those the result of septic infection following childbirth. This, of course, is in accord with the observation of others. A tube through Douglas' culdesac has offered the best means of drainage in these cases. As will be seen by reference to case histories, however, those of my cases treated by the ice coil without operation have resulted favorably. In a number of my later cases I have resorted to the use of mixed vaccines, and wherever possible to the use of autogenous vaccines, routine method being the administration of from 7½ to 15 c.c. of vaccine immediately following the operation, a second dose being used upon the second or third day, and thereafter doses at intervals of from two to four days, depending upon the extent and character of the reaction produced. Where satisfactory autogenous vaccines could be produced these have been utilized as soon as they were manufactured to the exclusion of the stock vaccines. My data is, as yet, altogether too limited to express an opinion pro or con as to the effect of this treatment upon the disease. In the thirty-nine cases I have had eleven deaths in this condition to date.

Case I.—This case was shown to the surgical section. S. S., man, aged 17 years. Duration of illness: 7 days. Physical examination: Rigidity and distension of entire abdomen. Symptoms of general peritonitis, with nausea, vomiting, constipation, extreme prostration. Temperature on admission, 105°, pulse 130, very thready, respirations 28. Blood examination: Leucocytes 28,000, polynuclears 94 per cent. Culture, streptococcus, and colon bacillus. Surgical findings: Gangrenous appendicitis, retrocecal appendix, general suppurative peritonitis. Operation: Patient was in such extreme shock that no effort was made to remove the appendix. Incision five inches in length in right rectus muscle. Profuse, greenish pus, very offensive, evacuated. Adhesive inflammation between coils of intestine forming pockets of pus throughout abdomen. Pus evacuated as far as possible; two large, fenestrated cigarette drains inserted. Condition of patient required infusion of 1,500 c.c. of normal saline to which two drams of adrenalin were added. Usual after-treatment applied, *i. e.*, ice soil, enemata of saline and whiskey, nothing by mouth, etc. Temperature for first five days following operation ranged from 101° to 106°, pulse from 110 to imperceptible. Second infusion on the evening of the third day, when temperature reached 106° and pulse became imperceptible. Twelve hours later, temperature 101°, pulse 120. Third infusion for same symptoms on the fifth day. Temperature for second five days ranged from 103° to 105°, pulse 120, respirations 28. On eighth day a fecal fistula became fully developed. This kept clean by high irrigation of 1:10000 permanganate of potassium solution three times daily. Rubber tube inserted to bottom of wound. At no time did patient complain of pain. Bowels moved cautiously by low enemata of rectal irrigation every other day. In this case absolutely nothing was given by mouth for thirteen days, thereafter small quantities of peptonoids, panopeptone and water, gradually increasing to peptonized milk and general fluids. Patient gradually improved. Was discharged with a small fecal fistula on the thirty-sixth day. The fistula closed of its own accord within two weeks.

Case II.—M. B., male, 38 years. Duration of illness: Three days. Physical examination: Pain, tenderness, rigidity, right abdomen. Condition on admission: Temperature 102.6°, pulse 120, full, bounding, respirations 30. Surgical findings: Gangrenous appendix, right-sided, diffuse, suppurative peritonitis extending from liver to pelvis. Operation: Excision, evacuation of pus, large, fenestrated cigarette dram. Blood culture, colon bacillus. First five days after operation, temperature 102°, pulse from 100 to 120. Usual after-treatment. Ten days after operation temperature, pulse and respiration normal. Uninterrupted recovery. Nothing by mouth for four days.

Case III.—M. H., woman, aged 28. Duration of illness: Two weeks. Sepsis after childbirth. Physical examination: Great distension, pain, involving abdomen nearly to umbilicus. Condition on admission: Temperature 103°, pulse 136, respirations 30. Blood examination: Leucocytes 7,200, polynuclears 74 per cent. I refused to operate on this case, but placed her on after-treatment already described, with the addition of vaginal douches, 116°, 1:10000 bichloride, every four hours, rectal irrigation each day and Fowler's enemata, as already described. I omitted to say patient was unable to keep anything on her stomach, and pain from the peritonitis was so intense that she had been kept under morphine before coming under my care for almost two weeks, with the usual effect upon secretions and excretions. Within six hours after beginning the ice coil and administering nothing by mouth pain completely disappeared and thereafter remained absent. Nutrient enemata were given alternately with Fowler's enemata in this case. Five days after temperature from 100° to 102°, pulse 100 to 120. Began the use of peptonoids and water in small quantities five days after admission, at this time removing the ice coil for twelve hours in each day. The effect of this was a slight rise of temperature and slight increase of pain. Fluids, beginning gradually, were now allowed. On the tenth day I endeavored to remove the ice coil, with a recurrence of temperature to 103°, return of pain. Both promptly disappeared within 24 hours upon the application of the coil. In this case the treatment, including ice coil, was continued for 21 days. The patient made a gradual, but uninterupted recovery. This case is practically identical with two other cases treated in the same way, except that the ice coil was used only for ten days in one case and two weeks in the other. I have omitted to mention that strychnine and whiskey were used liberally in all these cases as indicated.

Case IV.—F. M., man, aged 36. Duration of illness: Eight days. Physical examination: Pain, tenderness, distension and rigidity entire abdomen. Condition on admission: Temperature 104°, pulse 126, respirations 40. Surgical findings: General septic peritonitis, streptococcus and colon bacillus. Operation: Incision and drainage. This man was alcoholic and weighed more than 225 pounds. First five days after operation temperature ranging from 101° to 105°, pulse from 120 to imperceptible. Infused on the fourth day 1,200 c.c. normal saline solution, 2 drams of adrenalin. Temperature twelve hours after 101°, pulse 110, soft, good force. Patient died on the sixth day from general suppurative peritonitis, with a flaccid abdomen without pain and with a moist tongue, having had no pain since the time of the operation. This I attribute to the use of the ice coil and the inhibition of everything by mouth.

Case V.—M. S., girl, aged 14. Duration of illness: Six days, with complete remission of symptoms, subnormal temperature and rapid pulse on the fourth day and sudden onset on the fifth. Diagnosis ruptured appendix and diffuse peritonitis. Physical examination: Pain, rigidity, distension, including entire abdomen. Condition on admission: Temperature 101.0°, pulse 120, respirations 40. Nausea, vomiting, considerable cough, slight expectoration. Blood examination: Leucocytes 12,000, polynuclears 94 per cent. Blood culture showed pneumococcus infection. Surgical findings: Diffuse suppurative peritonitis, with thin, greenish pus, appendix congested, but not gangrenous. Operation: Excision, free drainage. Usual after-treatment. Infusion 800 c.c. normal saline with 1 dram of adrenalin on the second day, given for shock and imperceptible pulse. The temperature never exceeded 101° in this case. Patient died on the sixth day with a subnormal temperature, pulse of 100, with a flaccid abdomen and without pain. Physical examination of the lungs showed no evidence of consolidation, but numerous rales and harsh breathing.

Case VI.—M. S., woman, aged 18. Duration of illness: Four days. Physical examination: Pain, tenderness, rigidity, right lower abdomen. Condition on admission: Temperature 103.6°, pulse 140, respirations 30. Surgical findings: Gangrenous appendix, g. s. p. (general suppurative peritonitis). Blood culture streptococcus and colon bacillus. Operation: Excision, drainage. First five days after operation, temperature 102.2°, pulse 112. Ten days after operation, temperature 100.6°, pulse 94. Usual after-treatment. Discharged cured.

Case VII.—O. B., male, aged 40. Condition on admission: Temperature 101.2°, pulse 84, respirations 20. Blood examination: Leucocytes 8,400, polynuclears 80 per cent. Surgical findings: Gangrenous appendix, g. d. p. Operation: Excision and drainage. Five days after operation, temperature 101°, pulse 120, respirations 32. This man developed a slight surgical pneumonia. Ten days after operation, condition normal. Patient was treated in the usual manner.

Case VIII.—J. S., male, aged 16. Duration of illness: Two days. Physical examination: Pain, tenderness, rigidity. Condition on admission: Nausea, vomiting, prostration. Temperature 102.4°, pulse 120, respirations 24. Surgical findings: Gangrenous appendix, beginning g. d. p. Operation: Excision, drainage. Condition five days after operation, temperature 102.2°, pulse 128, respirations 26. Usual treatment. Discharged cured.

Case IX.—J. A., girl, aged 13. Duration of illness: Eighteen days. Physical examination: General rigidity and pain, vomiting, extremely septic. Condition on admission: Temperature 103.4°, pulse 102, respirations 28. Blood examination: Leucocytes 18,600, polynuclears 92 per cent. Blood culture colon bacillus and streptococcus. Operation: Owing to the condition of the patient, only wide incision, evacuation and drainage was attempted. A secondary operation was done on the fourth day to admit better drainage. Temperature 106.4°, pulse 120, respirations 28. Intravenous infusion of 800 c.c. normal salt solution with one dram adrenalin with usual effect on pulse and respiration. Blood examination now showed 9,600 leucocytes, polynuclears 88 per cent., showing a failure in resistance on the part of the patient to the infection. Patient died on the eighth day without pain, with a moist tongue and flaccid abdomen.

Case X.—P. V., male aged 24. Duration of illness: Three days. Physical examination: General abdominal pain, worse on the right side, with extreme rigidity. Condition on admission. Temperature 103°, pulse 96, respirations 24. Blood examination: Leucocytes 23,000, polynuclears 92 per cent. Surgical findings. Ruptured appendix, general peritoneal involvement, not much pus. Operation: Excision, drainage. First five days after operation, highest temperature 100°, pulse 72, respirations 24. Usual after-treatment. Discharged cured.

Case XI.—B. B., woman, aged 22. Physical examination: Abdominal tenderness and rigidity, right side, low. Condition on admission: Temperature 101.4°, pulse 80, respirations 20. Surgical findings. Ruptured appendix, abscess involving right abdomen liver to pelvis, walled off. Operation. Excision of appendix and right ovary. Usual after-treatment. Discharged cured.

Case XII.—T. S., male, aged 27. Duration of illness: Three weeks. Physical examination. Marked general tenderness, no rigidity. Condition on admission: Temperature 96.4°, pulse 72, respirations 18. Surgical findings: Ruptured, gangrenous appendix, g. s. p. Blood examination in this case showed 11,000 leucocytes, 71 per cent. of polynuclears. Operation: Excision and drainage. First five days after operation, temperature 101°, pulse 80, respirations 20. Usual after-treatment. Discharged cured. In this curious case I am inclined to think the patient would have gotten well by any rational method of treatment.

Case XIII.—J. M., male, aged 58. Duration of illness: Six days. Physical examination: Pain, tenderness, right-sided rigidity. Condition on admission: Temperature 101°, pulse 120. Blood examination. Leucocytes 27,200, polynuclears 82 per cent. Surgical findings: Appendicitis, g. d. p. Operation: Incision. Appendix not removed. Free drainage. Five days after operation, temperature 104.3°, pulse 180, respirations 36. Infusion 1,400 c.c. normal saline solution, with 2 drams of adrenalin, was administered, with the usual result in pulse, temperature and respiration. On the eleventh day temperature was 103°, pulse 128, respirations 32. Second infusion was administered with the usual result. In this case the ice coil was retained for two weeks. After-treatment as usual. Patient discharged cured.

Case XIV.—J. M., male, aged 38. Duration of illness: Emergency. Condition on admission: Shock. No blood count. Temperature 98.6°, pulse 100, respirations 20. Surgical findings: Blood culture showed streptococcus. Mixed vaccines were used in this case. Operation: Ruptured appendix, intestinal obstruction, general peritonitis. Little pus. Adhesions separated. Appendix removed. Five days after operation, temperature 102.2°, pulse 108, respirations 34. Ninth day, temperature 105°, pulse 128, respirations 24. Infusion of normal saline 1,000 c.c., 2 drams of adrenalin administered, with usual result in temperature and pulse. The partial intestinal obstruction was our chief foe in this dase. Oleum tigli was resorted to, as already described in my article, on the ninth day, with satisfactory result as to the bowels, but with the effect shown on temperature. Patient died on the thirteenth day with intestinal obstruction and very septic.

Case XV.—D. G., male, aged 23. Duration of illness: Four weeks. Physical examination: Rigid-

ity on the right side, general pain over the abdomen. Condition: Temperature 101°, pulse 84, respirations 26. Operation disclosed tubercular appendicitis and general tubercular involvement of the peritoneum, considerable free fluid. Appendix removed. Intestines and abdomen washed out with 50 per cent. peroxide of hydrogen, afterward flushed with saline solution. Patient sewed up without drain. Discharged on the twelfth day cured. This case really should not be included in my list.

Case XVI.—C. T., male, aged 18. Duration of illness: Repeated attacks extending over five months. Condition on admission: General abdominal pain, worse on the right side, tenderness, slight rigidity. Temperature on admission 103.4°, pulse 76, respirations 18. Blood examination: Leucocytes 16,000, 84 per cent. of polynuclears. Operation: Large retrocecal abscess extending to liver, right-sided, g. d. p. Operation: Excision and drainage. Five days after operation, temperature 103.2°, pulse 100, respirations 30. Autogenous vaccines used in this case. This patient was in the hospital sixty days. His temperature on the thirty-second day was 102 2/5°, pulse 108, respirations 24. He established a fecal fistula, which reopened twice. I am under the impression that the establishment of this fecal fistula added greatly to his chances of recovery.

Case XVII.—M. S., male, aged 16. Duration of illness: Two days. Condition on admission: Tenderness and rigidity, nausea, vomiting, extreme prostration, pain over entire abdomen and distension. Surgical findings: Temperature 104°, pulse 100, respirations 32. Blood examination: Leucocytes 12,000, 90 per cent. of polynuclears. Operation: Excision and drainage. First five days after operation, temperature 100 2/5°, pulse 80, respirations 28. Usual after-treatment. Discharged cured.

Case XVIII.—N. G., male, 51 years. Duration of illness: Eleven days. Condition on admission: Pain, tenderness, right-sided rigidity. Surgical findings: Temperature 99.6°, pulse 70, respirations 28. Blood examination: Leucocytes 30,000, polynuclears 86 per cent. Operation: Excision and drainage. Gangrenous appendix, g. s. p. Five days after operation, temperature 102.6°, pulse 140, respirations 32. Intravenous saline infusion, 1,400 c.c., 2 drams adrenalin. Usual after-treatment. Patient discharged cured.

Case XIX.—C. V., male, aged 36. Duration of illness: Four days. Condition on admission: Pain, tenderness, rigidity. Surgical findings: Temperature 101.8°, pulse 96, respirations 24. Blood examination: Leucocytes 22,000, polynuclears 94 per cent. Operation: Excision, drainage. Peritonitis with a little pus, adhesive inflammation, streptococcus infection. Patient progressed normally after usual after-treatment. Discharged cured.

Case XX.—J. T., male, aged 53. Duration of illness: Two or three weeks. Speaks no English. Difficult to get history. Condition on admission: Pain and tenderness, right side. Surgical findings: Temperature 101.2°, pulse 90, respiration 24. Blood examination: Leucocyte count normal. Operation: Excision, drainage. Beginning general peritonitis. First five days after operation, temperature 100°, pulse 92, respirations 20. This patient was reopened and drained on the thirteenth day. Temperature of 102.2°, pulse 120, respirations 24. Leucocytosis 18,000, polynuclears 70 per cent. Thereafter his convalescence was uneventful.

Case XXI.—A. C., male, aged 55. Duration of illness: Four weeks with remissions. Condition on admission: Pain, tenderness, rigidity, nausea, vomiting, constipation. Temperature 102.2°, pulse 88, respirations 30. Blood examination: Leucocytes 18,000, polynuclears 75 per cent. Operation: Ruptured appendix, g. s. p. First five days after operation, temperature 102°, pulse 108, respirations 28. Ice coil was applied for ten days in this case. Other treatment as usual. Patient discharged cured.

Case XXII.—F. C., woman, aged 23. Duration of illness: Twenty-four hours. Condition at time of operation: Extreme shock, abdominal tenderness and intense pain radiating from the umbilicus. Temperature 90.4°, pulse 140, respirations 36. No leucocyte count was made. (I have shown this case at the academy.) Operation showed a perforated gastric ulcer with general diffuse peritonitis, considerable amount of pus in gastric contents. Patient made an uninterrupted recovery, practically without temperature. Infusion of 1,400 c.c. of normal saline intravenously administered, with 2 drams of adrenalin, given on operating table. Ice coil applied for three days. Patient discharged cured.

PRACTICAL POINTS IN THE DIAGNOSIS AND TREATMENT OF DIPHTHERIA.*

BASED ON OBSERVATIONS OF FOUR HUNDRED CASES.

By ABRAHAM LEVINSON, M.D.,

CHICAGO, ILL.

RESIDENT PHYSICIAN, CHICAGO CONTAGIOUS DISEASE HOSPITAL.

Diphtheria is beyond doubt the best known among the infectious diseases, yet it is surprising how much uncertainty there exists in the diagnosis and treatment of this disease. Every physician knows the cardinal points in the diagnosis of diphtheria, yet cases of diphtheria are only too often diagnosed as tonsillitis, scarlet fever, pneumonia, and even typhoid. Every physician knows the fundamental factors in the treatment of the disease, yet many a case does not recover because of lack of antitoxin or failure to intubate. There seems to be a good deal of haziness on the practical points in the diagnosis and treatment of diphtheria, due to a great extent to the fact that the textbooks on the subject are not sufficiently clear on the matter. I shall here attempt to discuss some of the most important practical elements that enter into the diagnosis and treatment of diphtheria, basing my statements on 400 cases of the disease that came under my observation at the Chicago Contagious Disease Hospital. I shall refer to some of the cases as I go along. A detailed account of others will follow at the end.

Diagnosis: Not enough care is exercised by physicians in taking cultures from sore throats. The diagnosis of tonsillitis is so often made in the absence of membrane, that it justifies the statement made by a medical authority that 40 per cent. of diphtheria cases are diagnosed as tonsillitis generally because of neglect in taking a culture. A culture should be taken from every sore throat, no matter whether a membrane is present or not, because, after all, the finding of Klebs-Loeffler bacillus is the only positive diagnostic point of diphtheria. An expert bacteriologist can tell the presence of Klebs-Loeffler bacilli from a smear taken from the

*Read before the West Side Physicians' Club, Chicago, November 9, 1911.

throat. The bacilli can be distinctly seen in many cases upon staining the smear with Loeffler's methylene blue (Fig. 1). This method of diag-

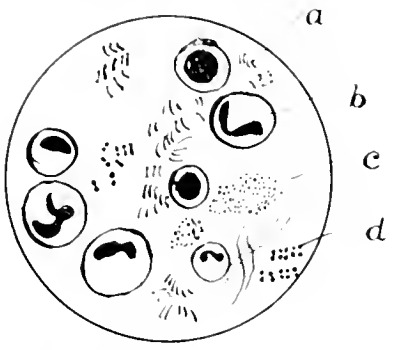

Fig. 1.—Smear from diphtheritic throat; *a*, Bacillus diphtheriæ; *b*, leucocytes; *c*, staphylococci; *d*, pneumococci.

nosis helps a good deal in the treatment, since antitoxin can be given immediately without waiting twelve hours for the incubation of the culture medium. Not all physicians are expert bacteriologists, however, and sometimes it is hard to differentiate *Bacillus diphtheriæ* from pneumococci, *Micrococcus catarrhalis*, or long bacilli found in the mouths of normal individuals. In general it may be said that no positive diagnosis should be made from a smear, and if the smear shows *Bacillus diphtheriæ* antitoxin should be given as a preventive measure anyway, but actual diagnosis should be withheld until the culture is examined. There are several important factors that should be considered in taking a culture from the throat: (1) The swab and the tongue depressors should be perfectly sterile. (2) The swab should be rubbed over the membrane, no matter where it is situated, in the nose, the tonsils, the fauces, or the uvula. If no membrane is present it is best to rub the swab over the tonsils, or between the tonsils and the anterior pillars; or if nasal diphtheria is suspected the swab should be carried backward to the nasopharynx. More than once have I seen physicians swab the inner surface of the cheek or the anterior surface of the tongue, and of course the result was a negative culture. (3) Precaution should be taken that no antiseptic or caustic has been applied to the tonsil at least an hour before the culture is taken. If such an application is made, whether it be iodine, silver nitrate, or listerine, it will cover up the bacilli and the result will be a negative culture, whereas in reality the patient has diphtheria, and toxin is disseminated all through the system as illustrated in Cases I and II. (4) The culture medium should be inspected before using, to see whether it is in good condition. If it is dry no growth will take place, and if its surface is rough or drawn over with a film (as happens when a growth of another bacterium has already taken place) the culture will be contaminated.

The culture requires at least eight hours of incubation, but wherever possible it is best to wait about twelve hours. If a regular laboratory incubator is not to be had, the vest pocket may be employed as such. Upon examining the culture the following day a good deal of information can be gathered from the appearance of the growth macroscopically. A diphtheria growth is usually 1 to 2 mm. thick, whitish in color, and evenly distributed, somewhat resembling the appearance of a diphtheritic membrane. A streptococcus growth, on the contrary, appears in the form of spots or dots unevenly distributed. Of course, no very positive diagnosis can be made on the appearance of the growth, but it helps in a good many cases. The appearance of the Klebs-Loeffler bacillus under the microscope is too well known to call for a detailed description. I shall, therefore, just note its most important characteristics. The Klebs-Loeffler is a curved bacillus about 3 mm. long, with strongly refractile material at either end, which stains more deeply than the rest. This material is known as the granule, and it is called so by laboratory men. There is nothing typical in the arrangement of the bacilli, but very rarely are they placed at obtuse angles to each other as the textbooks so commonly state. In a typical case of diphtheria it is usually easy to identify the Klebs-Loeffler, but in a non-typical case great difficulty is sometimes encountered in differentiating *Bacillus diphtheriæ* from other bacteria similar to it. Pseudo-diphtheria bacilli are sometimes mistaken for diphtheria bacilli, but the two can be distinguished from each other by the fact that the former is shorter and plumper and more uniform than the latter, and is free from granules. The Hay bacillus also has to be differentiated from the diphtheria bacillus quite often. In our hospital we had seventy-five culture media contaminated with Hay bacillus. The first few cultures were taken for diphtheria bacilli, but the size and manner of staining aroused suspicion, and upon closer examination they were all found to be Hay bacilli. Differentiation between the two becomes an easy matter, however, when one keeps in mind the fact that the Hay bacillus is much longer and thicker than the diphtheria bacillus, and that it contains spores which are quadrilateral in shape (Fig. 2). Sometimes it is difficult to differentiate

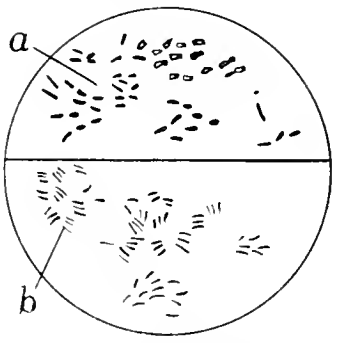

Fig. 2.—The Hay bacillus (*a*) an organism frequently confused with the diphtheria bacillus (*b*).

between the diphtheria bacillus and two pneumococci, the *Micrococcus catarrhalis*, or even streptococci (Fig. 3). It is therefore advisable to keep all these facts in mind when examining a culture.

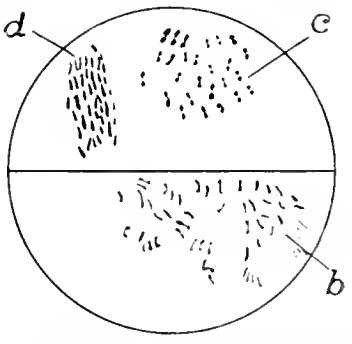

Fig. 3.—Pneumococci (*c*) and streptococci (*d*) sometimes confused with the diphtheria bacillus (*b*).

In a large city all these difficulties can be avoided, as the culture can be sent directly to the laboratory of the health department. Yet it is a very good

plan for the physician to examine the culture himself and thus lessen the chances of a mistake that can so easily be made in a large laboratory. To insure certainty several cultures should be taken before a diagnosis is made. Even if the first two cultures give a negative result, a third should be made, for it very often happens that the last result is the very opposite of the first two, as shown in Cases I and II. At our hospital we discharge diphtheria patients after two successive negative results, but if they are patients that have never had a positive culture we test them for three negatives before we allow them to leave.

Besides the laboratory diagnosis of diphtheria there are several clinical points that hold good in most cases and that help in establishing the diagnosis of the disease. (1) Diphtheria smell: A diphtheria case gives a very characteristic odor like that of feces. When one once becomes accustomed to the odor, one can easily detect a diptheria case at a distance of 2 feet. It is really surprising that clinicians who have written on diphtheria have never made any mention of this diagnostic point. The odor is most pronounced in nasal cases and less so in tonsillar, but is present in all cases. A clinical diagnosis can be made in all cases from the odor. (2) Temperature: Any case of sore throat with a temperature higher than 101.5 can safely be put down as a case of tonsillitis. No case of diphtheria runs up a temperature above 101.5°. A very severe case, especially if it is a nasal one, shows hardly any rise in temperature, most nasal cases having but 99°. It frequently happens that the administration of antitoxin raises the temperature to about 102° or more, but this disappears in a few hours. On the average the temperature in diphtheria is as follows: tonsillar, 101°; pharyngeal, 101.5°; nasal and laryngeal, 99°. (3) Membrane: Though no positive diagnosis can be made on the presence of a membrane, it can be taken as one of the best clinical diagnostic points in diphtheria. When a membrane appears on the tonsils, uvula, or posterior nares, one can safely diagnose the case as one of diphtheria. The absence of a membrane does not exclude diphtheria but its presence speaks for it. As stated before, however, if caustics have been applied to the tonsils they present an appearance of a diphtheritic membrane (Case III). Care should also be exercised to see that the tonsils have not been removed two or three days previous to the examination. Many a case of posttonsillectomies has been mistaken for diphtheritic membrane. Cases sometimes show what looks very much like a pharyngeal or laryngeal membrane, but on close examination it proves to be an ulcer of some kind, tuberculous, cancerous, or syphilitic, as illustrated in Case IV. Mistakes of this nature can be avoided, however, by a careful history and examination. (4) Retraction of epigastrium: In children laryngeal diphtheria is a very common type of the disease. It is always wise, therefore, to observe the manner of breathing to see whether there is any retraction of the epigastric region. If retraction is present the case may safely be diagnosed as one of laryngeal diphtheria, and antitoxin should be administered immediately. Very often a laryngeal diphtheria is mistaken for pneumonia, and the patient dies as a result of failure to intubate. Case V illustrates this point. (5) Nasal discharge: All nasal discharges in children should be suspected as due to diphtheria. Many a case of nasal diphtheria has been taken for a "cold" till it was too late to do anything. It is therefore advisable to take a culture from every nasal discharge to be sure that it is not diphtheritic in character.

Treatment: The whole medical world, with the exception of a few cranks, recognizes antitoxin as the life-saving measure in diphtheria. The amount of antitoxin to be administered is a point on which medical authorities differ, however, and in fact there seems to be a great deal of uncertainty in the matter. For instance, a physician gives 5,000 units in a nasal or laryngeal case, and then he wonders why the patient does not recover. The reason is not far to seek—it is plain that the child did not receive enough antitoxin. Our work at the Contagious Disease Hospital has taught us several things that can almost be laid down as rules: (1) A prophylatic dose should not be less than 5,000 units. (2) Curative doses in tonsillar diphtheria should be not less than 10,000 units. (3) Curative doses in nasal or laryngeal cases should be not less than 25,000 units. This has been borne out by clinical experience and I am confident of the truth of this statement. Never be afraid of giving too much antitoxin. If the heart does not degenerate as a result of the diphtheria toxin the antitoxin will not do it any harm. We have cases on record that have received as high as 85,000 units and have recovered without any bad effects on the heart. Cases VI and VII will illustrate this point. It is well to wait about eight hours between each injection, but in cases where the antitoxin is needed badly six hours will do. As for the place of injection, that is pretty much a matter of personal opinion. My experience has taught me that the gluteal region is the best for injection, as in this region absorption takes place most rapidly and the pain is less severe than in the scapular region. Always rub the spot of injection with bichloride solution or with alcohol to prevent the formation of abscesses. The tips of the hypodermic needles should not be touched by the fingers for the same reason.

Drugs: Like every other infectious disease diphtheria produces some pathological changes in the mucous membrane of the stomach and the intestine, and the physician should see that the residue of undigested food is removed in some way or other. The best drug for the production of catharsis is calomel, especially in children who can stand as high as one grain of calomel in one dose. In adults the drug should be followed by one ounce magnesium sulphate the next day. In the later stages of the disease, when catharsis is indicated, castor oil is better than calomel because of its soothing effect on the bowels, particularly if a hemorrhage of the bowel seems to be threatening. Nearly all cases need stimulation in one form or another in the course of the disease. Whiskey in twenty-drop doses every four hours seems to have a very salutary effect on children two or three years old, and it can safely be administered throughout the course of the disease. It is hard to give a real explanation of the mode of action of this drug, but it seems to help in loosening the membrane, and it also has a stimulating effect on the nervous and circulatory systems. Later in the disease, or if the pulse gets weak, one should give strychnine sulphate in 1/200 to 1/100 grain doses to a child of three or four years of age, increasing the dose according to the age of the patient. It is not a good idea, however, to administer strychnine too

early in the course of the disease. Outside of calomel, whiskey, and strychnine there are no other drugs, to my knowledge, that influence diphtheria favorably.

The routine treatment of a case of diphtheria can then be summed up as follows:

Tonsillar:—(1) antitoxin, 5,000 to 10,000 units; (2) calomel, 1 grain in divided doses; (3) magnesium sulphate, 1 ounce for an adult; (4) whiskey, 20 drops to 1 dram, according to age; (5) strychnine sulphate, if the pulse is weak.

Nasal case:—(1) antitoxin, 25,000 units; (2) calomel, magnesium sulphate, whiskey; (3) nasal irrigation twice a day.

Laryngeal:—(1) antitoxin, 25,000 units; (2) calomel, magnesium sulphate, whiskey; (3) intubation when indicated.

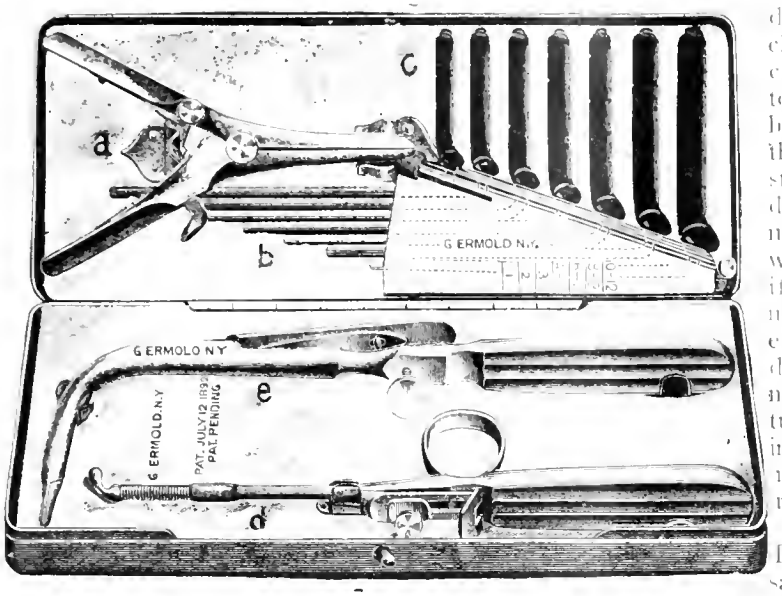

Fig. 4.—Ermold O'Dwyer intubation set; *a*, mouth-gag; *b*, obturators; *c*, hard rubber tubes; *d*, introducer; *e*, extubator.

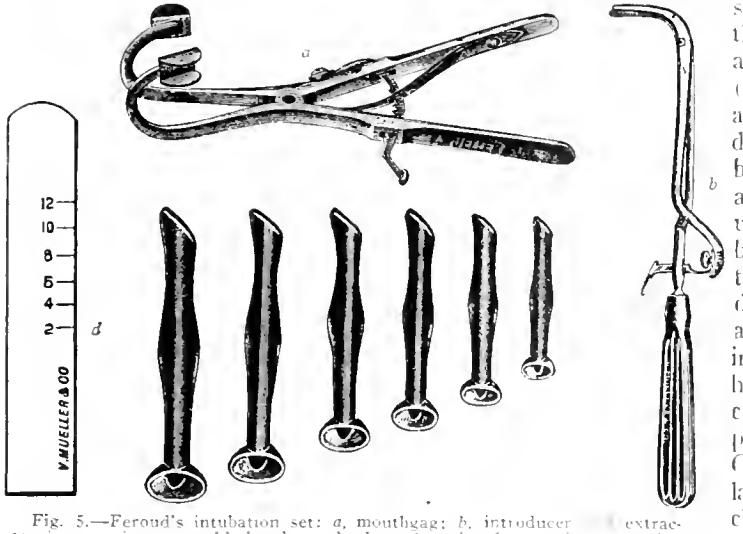

Fig. 5.—Feroud's intubation set: *a*, mouthgag; *b*, introducer and extractor in one piece; *c*, gold-plated metal tubes; *d*, scale of years for measuring the sizes of the tubes.

The laryngeal cases seem to be the bugbear of the general practitioner. Indeed these constitute the hardest type of diphtheria to treat. I shall, therefore, attempt to outline this type of the disease more fully. When the disease is seen early in its course and a slight croupy cough manifests itself, together with a marked hoarseness, 10,000 units of antitoxin should be administered immediately and the same dose should be repeated within eight hours. This will in most cases do away with the need of intubation. When seen later, when the child is gasping for breath and retraction of the epigastrium is evident, no time should be lost in applying hot poultices to the neck. Then the child should be intubated immediately. Intubation is indicated whenever the child does not get enough air to breathe as the result of obstruction of the larynx. This is evidenced by the retraction of the supraclavicular and epigastric region; the child brings all his accessory respiratory muscles into play, yet he cannot breathe well. Hospital attendants use the slang phrases, "he is going like a steam engine," or "he is sawing," to designate this condition in all its vividness. Intubation should be employed without delay in such a strait, no matter if it will be necessary to extubate immediately afterward. Intubation, if even for a minute, serves the purpose of dilating the larynx and loosening the membrane. Many a time did we intubate cases that had to be extubated immediately afterward, but upon removal of the tube the whole laryngeal membrane followed with it and the child got along very well after the operation. To fully convince oneself of the life-saving power of intubation, all one needs to do is to go into one of the wards of a diphtheria hospital and see the scores of patients that come in at the very point of death; in fact, some have even ceased to breathe, but the minute a tube is introduced into their larynx they begin to breathe very easily, and before long they recover completely. (See Cases VIII and IX.) As for the kind of instrument to be used, this is pretty much a matter of personal opinion. An expert intubator should be able to use the Feroud or the O'Dwyer set equally well. It is hard to say which is the better, as both have their advantages and disadvantages. The O'Dwyer tubes (Fig. 4) have the advantage of being light, as they are made of hard rubber, which does away with pressure on the vocal cords, but it has been found that this is not always a good thing as the child can cough the tube up too easily, especially when the disease becomes chronic (Case X). The Feroud tube (Fig. 5), on the other hand, can be depended upon to stay in place much longer, as it is wider in circumference and heavier in weight, but it has its drawbacks, as it has a tendency to produce pressure necrosis. A compromise between the two will probably give the best results. The O'Dwyer set can be used in all acute laryngeal cases and the Feroud in all chronic tube cases.

Technique of Intubation: The patient is placed on an ordinary table, in the recumbent position. A sheet is wrapped around him and pinned tight to prevent his struggling. The head is moved to the edge of the table where an assistant stands to keep it fixed. A mouth gag is then put into the mouth and held firm at the end to prevent slipping and biting of the operator's fingers. The index finger of the left hand is then introduced into the mouth

and pharynx till the tip of the epiglottis is reached. This can be ascertained either by the feel of a hard cartilage, the cricoid, or by the appearance of a cavity which is the esophagus, the epiglottis covering the larynx. The epiglottis should now be pulled up toward the operator so as to uncover the larynx. The introducer, held in the right hand between the thumb and ring finger, ready for use, is now introduced into the larynx, while the index finger pushes forward the spring of the O'Dwyer intubator or loosens the spring of the Feroud introducer which inserts the tube. The index finger of the left hand feels the tube in position and the introducer is then taken out. The mouth gag should be held in position until the thread of the tube is cut and pulled out. The mucus is then wiped out and the mouth gag is removed. The whole operation can be done in less than a minute by an expert operator, but that is no reason why the amateur should be discouraged if he fails to get the tube in the first time he attempts it. The only precaution to be taken, however, is to see that there is a thread in the tube and that the end of it is wrapped around the index finger. If this is done the tube can easily be pulled out immediately in case it is inserted into the esophagus by mistake. This applies to the expert intubator as well as to the novice. As soon as the physician is sure the tube is in place he should cut the string. It is unwise to leave the thread on, as in most cases it is found that the child has a tendency to chew the string and in doing so he often pulls out the tube and thus necessitates immediate reintubation. It is easy to ascertain whether the tube is in the larynx by the characteristic cough that is heard right after the tube finds its way into the larynx. The cough has a metallic ring and once it is heard it is easy of recognition. A further sign of corroboration that the tube is in the right place is the fact that the child cannot talk any louder than a whisper. Another manifestation of the same fact is the ease with which the child begins to breathe and the added color he takes on in a minute or two. An intubated patient should be watched closely all the time to see that he does not cough up the tube and that the tube does not become clogged up. If the tube does clog up the child should be extubated immediately. This is one of the reasons why it is unwise to treat an intubated case at home, and why it is best to have it taken to a hospital where it can receive the proper attention; where an expert intubator can be on hand in case of an emergency; where trained nurses are present to give the patient the required amount of care and feed him as he should be fed under the circumstances. Liquids only should be administered to all intubated cases, but even they are not taken well by the patient as they seem to bring on a fit of coughing. The best method of administering nourishment is the Casselberry, which insists that the patient's head be lower than his body while he drinks. Another point to bear in mind is the amount of stimulation an intubated case demands. Whiskey in 15 to 20-drop doses, every four hours, is probably the best drug to administer. In addition, the patient should be kept in a warm and, at the same time, well ventilated room, and if steam can be generated so much the better for him. All the time that the tube is in, antitoxin should be administered until an amount at least 25,000 units has been administered. Just how long the tube should be allowed to stay in the larynx is a point of great controversy. Still it can be said that the tube should be allowed to remain for about three or four days, and if the patient does not cough it up during that time he should be extubated. Extubation is indicated in all cases where the tube clogs up so that the child does not get enough air. In such a case extubation should be followed by reintubation. Atmospheric conditions also play a rôle in extubation. It is found that cases extubated on dismal days need reintubation.

Technique of Extubation: The patient is put on the table, wrapped in a sheet which is pinned tightly around him. The mouth gag is put into the mouth the same as for intubation. The operator, who stands on the right of the patient, introduces the index finger of his left hand into the mouth of the patient and pulls the epiglottis backward. The extubator, which is held in the right hand, is then introduced into the opening of the tube, and the handle is pressed upon, which causes the tips of the extubator to be pulled apart. The extubator is then lifted upward and at the same time drawn backward until it comes out together with the tube. To facilitate the introduction of the extubator, it is a good idea to use the index finger of the left hand to steady the tube in the larynx. Precaution should be taken, however, not to put the hand over the tube, as this will shut off the entrance of air into the larynx and the patient may be asphyxiated. The tube of a patient that has been extubated should not be discarded, but should be at hand with the string attached and obturator ready for use at any instant for a reintubation, if such should be necessary. Lejars, in his "Urgent Surgery," describes the Bayeux method of extracting the tube from the larynx. "The nurse charged with the enucleation is seated opposite the child, whose head she holds with one hand, in such a manner that the fingers are on the occiput and the thumb is in front of the forehead. The other hand encircles the patient's neck, the ball of the thumb being applied to the lower border of the cricoid cartilage, behind which the lower end of the tube lies. The operator draws the child's trunk toward himself so that it makes approximately an angle of 45 degrees with the horizontal plane; the head being fixed, it is naturally strongly extended by this movement. The nurse then, with the thumb, which is applied to the trachea, makes moderate but persistent pressure on it until the intralaryngeal tube is felt to slip away; the hand applied to the child's head immediately depresses it, so that the face is directed toward the floor. At the same moment the child is told to spit, and almost invariably the tube is expelled from the mouth." We have several times attempted this method of extubation, but only once have we been successful. It seems to me that an expert can do an extubation with the regular instruments in less time and with less trouble than is entailed in the above method. Still the plan Lejar describes is well worth trying in cases where the extubator does not work well for some reason or other.

Tracheotomy: Although the operation of tracheotomy is very much favored in Europe, it is falling into disfavor in this country and is being used less and less each year. There are several reasons for this: first, there is great loss of blood as a result of the operation, and second, the patient must bear the scar that is left for the rest of his life. The principal argument against the performance of a tracheotomy is the fatality that so frequently follows. Very few tracheotomy patients live through

the operation, and the few that do survive it live hardly more than several days after the effect. Tracheotomy should, therefore, be resorted to only after all other means of supplying air to the patient have been exhausted. I should consider the following conditions indications for a tracheotomy: (1) When the whole pharynx is blocked up by a membrane and no air can come through and enter the larynx. In such a strait intubation is of little use as the obstruction is not in the larynx, but above it. (2) When the membrane in the larynx is so thick that it clogs up the tube immediately and causes it to be coughed up as soon as it is introduced.

Preparation for the Operation: First of all the tracheotomy instruments are to be examined to see if they are perfectly sterile as for any other operation. They are also to be ready for use at any moment in all hospitals where diphtheria cases are treated, for the operation is nearly always one of emergency, and no time is therefore to be lost in boiling the instruments. The instruments needed for the operation are: (1) scalpel, (2) artery forceps, (3) two blunt hooks, and (4) a tracheotomy tube with tape attached to end. No needles or catgut are necessary as the wound heals much better when it is not sewed up. Nor is a general anesthetic needed for a tracheotomy. A 4 per cent. cocaine solution applied around the place of incision will do. In fact, I have frequently done a tracheotomy without the use of any anesthetic.

Technique: The patient, wrapped in a sheet, is put on a plain table and his head is brought to its edge where it is steadied by an assistant. It is well to put a roll of sand bag under the patient's neck so as to extend the head to the greatest degree. This helps to make the trachea tense and to steady it. The surgeon, who stands at the right of the patient, feels the tracheal rings and ascertains the position of the thyroid body and the cricoid cartilage. A vertical incision is made in the median line from the upper border of the cricoid cartilage to three-quarters of an inch beneath it. The skin, the subcutaneous fascia, and the anterior layer of the cervical fascia are separated at the first cut. The sternohyoid and the sternothyroid muscles are next separated by forceps or the blunt side of the scalpel. A blunt hook is put on each side of the wound and one above it to keep the isthmus of the thyroid body downward. The fascia covering the trachea is then cut, exposing the tracheal rings. Now the surgeon, holding the trachea with the fingers of his left hand, stabs two tracheal rings with the scalpel, which he holds in his right hand. A rush of air into the wound and an expulsion of mucus indicate that the trachea has been cut. The wound is now dilated by a pair of forceps and the tracheal tube is slipped in and pushed downward. The tape at the side is now brought around the neck and tied so that it holds the tube in position. No sutures are necessary for the coaptation of the wound. The wound heals better when left to itself, for the introduction of the suture very often causes suppuration.

All tracheotomy cases should be watched carefully: the inner tube should be cleaned every morning, and the outer tube should be taken out and cleaned at least once a week. The wound should be kept aseptic as any other surgical wound. The room in which the patient lies should be kept perfectly free from dust to prevent the getting of aspiration pneumonia. The tube should be allowed to remain in its place for two or three weeks until the cause that necessitated its insertion is removed. At the end of that time the tube may be removed, but if the child cannot breathe as well as he should, he should be reintubated. The sooner the tube is taken out the better, however, for the patient, for it has been found that the larynx undergoes atrophy when not in use (see Case X).

Treatment of Complications: Diphtheria has many complications. It is surprising to note how many cases recover from the original disease, but die from some consequent complication. The most unpardonable thing about such cases, however, is the fact that they could easily be prevented if they were watched carefully enough and if the complications were looked out for. I shall limit myself to a discussion of the prophylaxis and treatment of these complications, leaving their pathology out of consideration.

Acute dilatation of the heart: A goodly number of cases of postdiphtheritic myocarditis can be prevented if the patient is kept in bed at least two weeks after the temperature returns to normal. It is necessary to remember that the diphtheria toxin produces a degeneration of the heart muscle, and that it takes a long time for the heart to return to its normal condition, and consequently any strain put on it will produce an acute dilatation of the heart. Case XI illustrates this very well. When acute dilatation of the heart occurs the patient should be put to bed immediately and digitalis in some form or other should be administered. If this treatment does not cause the heart to return to its normal condition the physician may start the use of strychnine.

Bronchopneumonia: Bronchopneumonia is another complication that can be prevented in a great majority of cases. The air of the room should be kept warm, but at the same time it should be well ventilated. If the room is also kept perfectly free from dust there is small risk of bronchopneumonia. If, however, the complication has taken hold, strychnine in doses of 1/200 of a grain every four hours should be administered to a child two to three years of age. If the child is not intubated syrup of ipecac in 10-minim doses can be given with beneficial results. If the child is intubated, the action of the ipecac may possibly make it cough out the tube.

Glands: In the winter many diphtheria patients develop suppurating glands. I know of no method of prevention, but when such a condition develops the glands should be lanced to prevent a general septicemia by absorption of the organisms in the blood. (See Case XII.) Discharge from the Ear: The ears of all diphtheria patients should be kept perfectly clean, otherwise a discharge, either diphtheritic or a mixed infection, is likely to develop. In such a case the ear should be cleaned with boric solution and carbolglycerine should be applied. If treated in this manner early in the stages of the infection, the discharge will clear up. Postdiphtheritic Paralysis: If sufficient antitoxin is given early in the disease no paralysis will develop. When not given early enough paralysis of the recurrent laryngeal or even of the pneumogastric nerve is very likely to develop. We tried electricity and massage in a case of paralysis, but nothing seems to be able to cure the case once paralysis has set in. The better plan is to prevent the onset by giving sufficient antitoxin at the proper time.

Following is a report of twelve cases:

Case I.—Miss M. R. Was taken with sore throat and pains in the limbs. Temperature 101°. Called in a physician, who painted the tonsils with silver nitrate. Two hours later the patient came to the hospital and a culture was taken from her throat. Upon examination the following day the culture was found to be a negative one. The same result followed the next examination the day after. On the third day, however, the culture was found to be pure diphtheria growth. The only reason the resident physician could give for the phenomena was that the application of the silver nitrate had given the negative culture. In fact it was soon discovered that such an application gives negative results when used on patients in whom the diagnosis of diphtheria has been established beyond doubt.

Case II.—Miss H. N. came into the hospital complaining of slight headache and sore throat. Culture was found negative the first day and also the second. On the third the culture was positive and it remained so for the next three months. The explanation for the first two negative cultures was given by the patient herself. She had been using a gargle of listerine recommended by her family physician.

Case III.—W. M., age 22, came into the hospital on October 13 with the following symptoms: headache, backache, chill, fever (101°), vomiting, and diarrhea. A membrane was seen over the whole pharynx. Patient gave a history of heavy drinking. A culture was taken and found to be highly positive. Thirty thousand units of antitoxin were injected and the temperature gradually subsided. The patient was dismissed from the hospital on October 24, after two negative cultures. On October 27 the patient was sent back to the hospital from one of the large hospitals in the city. His case was diagnosed as diphtheria on the appearance of a membrane. The right tonsil also looked as if it were covered with a membrane. We questioned the patient and he told us that a doctor had applied 50 per cent. carbolic acid to his tonsil, which revealed the secret of the membrane. We then took a culture from the patient's throat with negative results. We continued taking cultures for six successive days and each time the result was a negative one. The patient was discharged as nondiphtheritic.

Case IV.—J. F., age 37. Previous history. Drank heavily. Had been tramping around the country for the last eighteen years. Patient gave a history of gonorrhea six years ago and chancre four years ago. Had diphtheria three years previous for which he was treated at our hospital. Symptoms: Felt pain upon swallowing. Pain radiated upward and downward. Complained of backache but no fever. His physician diagnosed the case as diphtheria. Upon examination the tonsils were found to be atrophied; the pharynx showed nothing abnormal. We made a laryngoscopic examination and found a large ulcer in the mucous membrane of the larynx, which we diagnosed by its appearance as syphilitic. Cultures taken from the throat were negative. The patient remained in the hospital for seven days and was given some antitoxin, but showed no improvement. He was then sent home on the basis of negative cultures.

Case V.—S. F., 3 years old. Was taken sick on October 2 with fever. Rapid breathing. Physician diagnosed case as pneumonia and assured parents that there was no danger. On October 3 there was great retraction of the epigastrium, which aroused the physician's suspicion that the case might be one of diphtheria. The ambulance was called and patient was hurried to hospital, but he died on the way because of lack of intubation. This is only one of many laryngeal diphtheritic cases that have been mistaken for pneumonia.

Case VI.—A. R., 42 years of age. Was brought into hospital on a stretcher. Pharynx blocked up by mebrane. Adenitis. Temperature 101°. Pulse 68. Respiration 28. A systolic murmur was heard at the apex, second pulmonic accentuated. Culture strongly positive. Antitoxin administered in 10,000-unit doses, until 85,000 units reached. Temperature dropped. Adenitis subsided and patient gradually recovered. Was kept in bed for three weeks because of her heart trouble. Discharged in very good condition.

Case VII.—H. N. Entered hospital August 28 with a severe adenitis resembling Vincent's angina and a pharyngeal membrane. Case was diagnosed by one attending physician as Vincent's angina, but the microscope did not reveal the vibrio, while it did show the Klebs-Loeffler bacilli. Steam inhalations were given in addition to big doses of antitoxin, until the maximum of 90,000 units was reached. Patient recovered without any bad effects on the heart. Was released September 20.

Case VIII.—N. W., 3 years old. When carried into hospital he looked as if he were dead. Still we decided to give him the benefit of the doubt and we intubated him. As soon as tube was introduced into larynx patient started to breathe and color mounted into his cheeks. After a three weeks' stay the patient was dismissed.

Case IX.—O. O., male 3 years old. Entered hospital July 21, 1911, with laryngeal diphtheria. Was intubated the night after admission and was extubated August 1, but had to be reintubated. Coughed up tube August 5 and got along without it for three days, when suddenly it was noticed that he began to breathe very heavily, and when physician reached his bedside he was cyanotic and had stopped breathing. A tube was put into his larynx with great difficulty on account of the collpase of the larynx. As soon as tube was in position, however, the child started to breathe and in a minute or two he was breathing easily. Since then he several times coughed up the tube and "went on the bad," as the nurses termed it, but as soon as the tube was introduced he recovered immediately. On November 7 after a trial of two weeks without the tube we discharged patient. This is but one of many cases where intubation was a life-saving measure.

Case X.—W. K. Male 10 months old. Entered hospital June 28, 1911, with laryngeal diphtheria. Pharynx was blocked up by membrane, but intubation did not relieve the retraction very much. A tracheotomy was performed. Child got along very well for two weeks. We removed the tracheal tube and introduced a plain tube into the larynx. The child coughed up the tube and had to be reintubated immediately. Had to be reintubated six times that day. We finally decided to try a metal tube, which we did, with good results. On October 19, when we extubated patient, we found that the larynx had atrophied. On November 1 bronchopneumonia set in and the child died from the effects of it on November 3.

Case XI.—J. B. Male 35 years of age. Entered hospital June 28, 1911, with a severe case of pharyngeal diphtheria. Examination of heart and lungs was negative. After an injection of 30,000 units of antitoxin the temperature went down and throat cleared up. On September 11 patient got out of bed and was suddenly seized with severe pain in the precordial region. His heart was percussed and found to be enormously dilated. He was put to bed and an infusion of digitalis was administered. Patient was not allowed out of bed until November 9, when he was discharged feeling fairly well and strong.

Case XII.—T. F., 3 years old. Male. Entered hospital October 1, 1911. Sick three days. Had no antitoxin. Diagnosis: laryngeal diphtheria. Was intubated immediately upon arrival. Received a dose of 10,000 units antitoxin, dose repeated in twenty-four hours. On October 3 an enlarged gland was noticed on the right side of the neck. Temperature rose from 100° to 103°. Gland was not opened, and in twenty-four hours the temperature was 104°. An application of tepid packs every six hours did no good. Infection of the index finger of right hand set in and went on until it developed into osteomyolitis. The finger was opened on October 5 and drained. On October 6 the entire hand was infected and suppurative foci developed all over the body. The patient gave forth a very septic odor and died October 21 from general septicemia.

RETROBULBAR OPTIC NEURITIS.

By SAMUEL HORTON BROWN, M.D.,

PHILADELPHIA.

Among the several vague conditions that ophthalmologists are called upon to diagnose and treat, none seems to offer any greater interest than retrobulbar optic neuritis. It is of special importance because it enables the opthalmologist to demonstrate that his branch of medicine is not merely a spectacle-prescribing trade, but is supplementary to general medicine. In the common form of the affection (chronic retrobulbar neuritis) the specialist is enabled to show to the patient and his physician that the several foreign substances that his economy is taking up are having deleterious effects upon the individual long before the physician is able to detect these effects by changes in other structures.

The condition is of great importance from another standpoint. The transportation companies throughout the civilized world give considerable attention to the examination of the eyes of their employees engaged in active service, with a view of determining the onset of those defects that interfere with vision and color perception. The most insidious of the conditions causing such defects is retrobulbar optic neuritis, and none shows earlier interference with color perception. Further, no class of employees is more frequently exposed to the causes that produce the affection than this class. It is unfortunate, but none the less true, that by the time an engineer of a train, for instance, becomes so highly proficient in his calling as to be of great value to his road, he has reached the age when his system is no longer able to dispose of the several poisons he is likely to encounter.

It is with great difficulty that the railroad men and their unions can be made to accept this fact, but this is not surprising when we consider how difficult it is for the medical profession at large to understand that it is the age of the patient plus the several poisons that produce the condition. Almost any one can be made to appreciate that a man 38 or 40 or 45, all other things being equal, is not so good a boxer, baseball player or football player as a man in the early twenties. The cause is largely the same. The various structures concerned in elimination are not so good as they once were. Fatigue may occur in varying grades, absolute exhaustion is not always necessary to demonstrate it.

While it is the province of the ophthalmologist to detect the condition, it does not imply that the acquiring of the technique of the ophthalmoscope will serve to enable the attendant to diagnose it. Many physicians have acquired a valuable working knowledge of that instrument, but would find it useless in this condition as the diagnosis is positively made by means of the perimeter, the correlation of the several ocular symptoms, and the exclusion of other conditions. Many of these cases are regarded as refraction cases. The fundus is examined and found negative. The patient fails to procure benefit or relief of the exasperating blind spot, and the attending physician puts it down to that overworked condition known as "mental astigmatism," and with a kind word or two dismisses the patient. The lesson to be derived from someone's else experience of this kind is that no case should be considered of so trivial a character as to deny it a complete investigation. It is very difficult to assume with accuracy negative conditions, and considerable embarrassment frequently results from so doing.

This is more especially true if the patient has been sent to the physician or ophthalmologist, as the case may be, since in such instances the frank symptoms have already been observed and recorded. Such cases call for detailed examination and only such physicians as have an elaborate and comprehensive examination technique at their finger tips can express an opinion of any value. This seems perfectly obvious, yet the medical departments of the larger railway companies of America restrict themselves to a most miserable equipment in this regard. The examiners engaged in this routine work, as a rule, are poorly paid and those that are attracted to the work consequently have but a meager knowledge of this phase of the examination, and are forced to content themselves with detecting gross defects. A clear knowledge of the condition is therefore of great value.

Orbital optic neuritis or retrobulbar neuritis is also known as central amblyopia, which as its name implies is central blindness. Hence any person complaining of a fixed black spot in the visual field is a subject for suspicion. The condition presents itself in an acute and a chronic form.

The acute is the less common of the two and is rapid in its progress, seldom requiring more than a week to complete its course. The black spot in the visual field appears suddenly and rapidly enlarges until the visual field is entirely or partially obliterated. This means complete or partial blindness, which may be temporary or permanent, depending upon a host of circumstances. Even a skilled ophthalmoscopist will, in most instances, be unable to detect for several days any abnormalities in the eyegrounds. As the blind spot increases the margins of the optic disk will be seen to be blurred and the surface will be hyperemic. The retinal arteries will appear contracted while the veins will be distended. The macula may show some changes, but nothing characteristic. The diagnosis will be made upon the

visual field and the subjective symptoms, which latter consist, in addition to the blind spot and increasing blindness, of tenderness of the globe on pressure and pain.

The pathology of the affection is a matter of speculation. It is assumed that the condition is an interstitial neuritis within the optic canal which restrains itself from extending either back into the optic tract or forward into the globe of the eye, and involves almost exclusively the papillomacular bundle of fibers, but may extend peripherally and affect the entire nerve. As in all inflammation of nerves, degeneration of the affected fibers is a most likely sequel. The ganglion cells of the macula share the degeneration. This affection appears to be almost selective in character if this view of the pathology is to be accepted. As there is no mortality connected with the disease, and it is consequently not amenable to post-mortem observation, there is at hand no scientific means of disproving this theory of the affection.

The causes of acute retrobulbar neuritis are toxic conditions in which the particular poison is present in the circulation in an overwhelmingly large amount. The system at large has had little chance to adapt itself to its influence and the results of its presence are correspondingly sudden and abrupt. The acute infectious fevers, especially influenza, are common causes of the condition. Inflammation of the several sinuses adjacent to the orbit is attended by the condition, and it is a question whether the affection in such instances depends upon contiguity of structure or upon the attendant toxemia from the pus and the diseased bone.

The affection has been observed in the course of acute menstrual disturbances, but just how this relationship is brought about is a matter of considerable speculation. Prolonged eyestrain produces exhaustion of the nerves of the eye and this will produce at times symptoms identical with acute retrobulbar neuritis. Certain nervous disturbances such as insular sclerosis and myelitis are at times likewise attended with this condition, and again, there is a certain proportion of cases in which no cause can be assigned.

Fortunately the condition is uncommon. Unfortunately it is likely to be confused with a definite acute optic neuritis, which is nearly always followed by optic atrophy and total blindness. The prognosis in acute retrobulbar neuritis will depend upon whether the affection tends to run towards this atrophic condition. Many cases are followed by only partial blindness, but total loss of vision is always to be feared.

Chronic retrobulbar neuritis is the variety of the affection that is often described under the names "tobacco-alcohol amblyopia" and "toxic amblyopia." This form of the disease usually makes its appearance about the age of forty or later, and its most prominent symptoms consist of marked reduction in vision which cannot be improved by the use of glasses. Central vision especially is affected, and although the peripheral vision may be almost normal, acute vision is deficient. The ophthalmoscope offers but little aid in arriving at a diagnosis. The temporal side of the disk may show some pallor, but there is nothing especially distinctive.

The use of the perimeter will render the diagnosis comparatively easy. The field of vision may be normal in extent, but central blind spots symmetrical in distribution and oval in shape, especially for red and green, will be the prominent features of the fields. The alteration of the fields is also attended with deficiency of the color sense. This disturbance of the color sense with its attendant relative scotomata render the disease important from a commercial standpoint. Skilled employees approaching middle life frequently make blunders that can be accounted for in no ordinary way, which might have been prevented by examination of their eyes by an ophthalmologist at the beginning of their presbyopia instead of by the "eyes examined free" and "no drops" kind of optician. Floating spots, clouds before the eyes and similar subjective phenomena in persons over forty should not be hastily dismissed with the explanation that they are due to disordered liver or eyestrain, but demand careful investigation.

The cause of this affection is to be found in the continued absorption of some toxic substance or substances, which should have been eliminated, but are retained on account of the diminished functional activity of the excretory organs incident to age. In practice it is found that alcohol and tobacco, either or both, usually both, used continuously in large quantities over a long period are the most common causes. Almost any other poison under the same conditions and circumstances will give rise to it. Quinine, lead, iodoform, chloral, bisulphide of carbon, etc., may be mentioned as examples. The toxins of the infectious fevers and constitutional disorders may produce the condition. As already mentioned, both eyes are usually involved. Bartenders, firemen, engineers and commercial travelers are especially liable to the condition.

As in the acute form the pathological change is believed to be an interstitial neuritis showing a special predilection for the fibers that go to the macula, the so-called papillomacular bundle. As with nerve inflammation elsewhere it is likely to follow a most prolonged course and the function of the nerve, at best, returns but very slowly.

Many of the cases present themselves in the course of chronic alcoholism and the symptoms urge the family and attending physician to greater vigilance. It seems scarcely worth while in the face of such an obvious course to pursue, to insist upon total abstinence from all forms of alcohol and tobacco. Oftentimes the discipline of a sanitarium is necessary to enforce this part of the treatment. Without such abstinence there is little hope of arresting the progress of the disease. The feeding should be given close attention and elimination of waste products should be encouraged. The iodides should be administered for their absorbent effect. Strychnine is especially useful and should be given to the limit of tolerance. In the early stages these simple measures persisted in will be followed by most gratifying results within six months or a year. When the blind spots are large and positive and the duration very long, the outlook is proportionately less encouraging. Dark glasses should be worn to protect the eyes, as the light may be very annoying.

The importance of the affection lies in its very insidious onset and absence of ophthalmoscopic signs. Hence in all persons over thirty-five in whom correction of ametropia has failed to relieve symptoms, the field of vision should be measured. A careful examiner will examine the fields in all cases, giving a history of failing vision and "spots" before the eyes. The extra work involved will be advantageous in that it may spare the attendant the possible embarrassment of having another surgeon detect the condition.

PSYCHOGENOUS AFFECTIONS IN SUBJECTS OF SOUND STOCK.

NEUROLOGISTS are especially interested in the study of exhaustion syndromes and affect syndromes in individuals entirely free from neuropathy. The tendency of the psychoneuroses to occur in so-called nervous degenerates is so pronounced that it seems difficult or impossible to conceive of their attacking the sound save under some most fortuitous combination of circumstances. Subjects thus afflicted are believed to undergo spontaneous recovery after rest and banishment of the causal factors; moreover, it is thought to be easy for them to avoid exposure to future attacks.

As a matter of fact, however, we often see epilepsy, hysteria, and traumatic psychoneuroses develop in the sound, but so far as we know no one has as yet devoted his full attention to the study of these affections in the healthy. One very satisfactory reason for this defect is bound up with the fact that patients of this type are seldom found in public institutions. Furthermore, it is rare to find full accounts of the traumatic psychoneuroses which follow some great catastrophe.

For this reason Stierlin's article in the *Deutsche medizinische Wochenschrift*, November 2, 1911, on the nervous and psychical disturbances actually known to have followed certain catastrophes, becomes of unusual interest. Survivors of six great recent events of this sort have been extensively studied. Italian medical men had abundant material after the Messini earthquake, and in like manner the survivors were studied on the spot at Valparaiso. The mining horrors at Courrières, France, and Radbod, Germany, destroyed nearly 1500 lives, and the after effects on the survivors received due and prompt consideration. The author has had personal experience with those who escaped death at the Müllheim railway accident and the fall of the partially constructed bridge at Brail.

It appears to be shown beyond all doubt that catastrophes produce upon quite sound individuals reactions otherwise encountered only in psychopaths. The author lays stress on this fact as possessing much significance. Beyond this statement he does not go, as it was hardly practicable to segregate those without predisposition. The inference is that the type of disorder did not differ radically in the normal and neuropathic subject. The entire article is highly instructive and the author's brief conclusions hardly do it justice. These are as follows: (1) Acute fright psychoses lasting several days were common, and these partook of the character of epileptic and hysterical twilight states; chronic forms of the same nature resembling exhaustion psychoses and Korsakoff's psychosis. (2) An acute vasomotor syndrome, stated by the author to be new among traumatic neuroses, made up of sleep disorders, a peculiar pulse (rapid and labile), and increased patellar reflexes, was studied; more infrequently were noted the ordinary phenomena of vasomotor disturbance (hot flushing, cold extremities, headache, vertigo, profuse sweats, dermographism). 3. Neuroses proper of more gradual development, hysteria and neurasthenia and some of the phenomena classed usually under psychasthenia were common. One writer is quoted as believing that periodic depression and cyclothymia are more prone to develop in the sound that are the acute phobias.

EUTHANASIA AGAIN.

MAETERLINCK, in his new book "Death," declares that all our knowledge but helps us to die in greater pain than the animal that knows nothing. As science progresses it but makes for a prolongation of the agony of death—the most dreadful and the sharpest peak of human pain and horror, at least for the witnesses. "All the doctors consider it their first duty to protract as long as possible even the most excruciating convulsions. Who has not, at a bedside, twenty times wished to throw himself at their feet and implore them to show mercy." The prejudice against the arbitrary induction of a painless and premature death will one day, believes the Belgian Shakespeare, be regarded as barbarian, as a "relic of the times when humanity was convinced that any known torture was preferable to those awaiting us in the unknown"; and he predicts that a day will come when science will no longer hesitate to shorten our misfortunes, "When life, grown wiser, will depart silently to its hour, knowing that it has reached its term, even as it withdraws every evening while we sleep, knowing that its day's task is done."

One hesitates to reopen this question whether physicians should purposely hasten the deaths of sufferers from painful diseases, or of those patients who would seem beyond recovery, and had therefore best be dead—a question which physicians must ever answer by a decided negative. But the views of a man of Maeterlinck's caliber cannot be slighted. And the wonderful skill and literary charm he evinces fascinate the reader, and give weight to opinions which might be ignored were they less beautifully and touchingly expressed. Yet, the author of "Pelléas et Mélisande" is a mystic, a poet and a dreamer of exquisite dreams—such a one the like of whom the world is ever in need of, and perhaps never more so than to-day. On the other hand it is essential for science—certainly for medical science—to deal ever with the hard facts of life; should science seek to evade its responsibilities in these premises, she would swiftly be brought to book—in the criminal courts, for

example. For it is not given to science to appoint herself, upon her own initiative, an executioner of human beings. Among the hard facts which science has to face are the following (which have to be reiterated in every opening of the euthanasia discussion): Physicians can never be sure that their prognoses of a fatal issue are absolutely infallible. People that have suffered from seemingly irremediable cancer, or from chronic tuberculosis, have attended the funerals of the doctors who have ministered to them in their "fatal" illnesses. To err in medical prognosis is human; only divinity can appoint unerringly the hour of death. Nor has the physician (nor any other mortal) any right to hasten a death upon his human assumption of its inevitableness. Again, what a weed-choked field of possibilities, criminal or otherwise, would be sown were such advocacy as this of Maeterlinck to prevail; were, for example, the physician overpersuaded by the specious pleas of heirs, or by the simulated pity of other individuals anxious to sever ties such as most of mankind find precious, to provide for the sufferer, before his appointed time, "a gentle and easy death."

The above quotations from the writing of him who this year most deservedly won the Nobel prize for literature make "copy" interesting indeed; yet it is to be feared they do not accurately express the situation. Physicians are not hardened men; there are none more sympathetic. The span of doctors lives averages shorter than in most other callings, and this probably because the sufferings of their fellow mortals take so much out of them. It is not essential in medical practice to prolong any convulsions, and there would never be the slightest occasion for any one on bended knee to implore the physician to alleviate sufferings. To relieve pain is a first principle in practice, and the physician is always justified in this course, in so far at least as the life of the patient will not be jeopardized by his ministrations. And the physician is ever eager to do this, if for no other reason than that there is hardly anything so killing as pain. As to the horror of death—this the spectators may have. But it is the rarest phenomenon for him who is about to die to "suffer" death. Immediately death impends, the end is almost invariably benignant and peaceful. What, indeed, is there in all the cosmos so composed and content as the face of the dead?

Osteomyelitis and Epithelioma.

Epithelioma is known to have an inflammatory precancerous stage in very many of its clinical forms, but few surgeons would connect it *a priori* with a chronic osteomyelitis, and few physicians would anticipate that cancer may be a sequel—even remote—of an acute infectious disease. A pathologist, of course, would at first sight deny that an epithelioma could possibly develop from bone marrow. It has been known for many years that typhoid fever has as a not infrequent sequence a bone lesion known as periostitis, osteoperiostitis, osteomyelitis, etc., according to the structure of the bone attacked. In more recent years it has been learned that the paratyphoid bacillus, the germ of influenza, etc., can set up the same lesion, and it is highly probable that the gonococcus, *Bacillus coli*, pneumococcus, in fact, any pyogenic germ can cause these bone lesions in the course of a bacillemia, however mild or latent the course. Moreover, we now know that such lesions may not appear until very many years after the original infection. Thus in one instance a patient evidently had a paratyphoid infection years before the germ of that disease was described. It was diagnosticated at the time as typhoid fever. The exact nature of the disease was revealed after 20 years, when a suppurating bone lesion developed, the pus of which was rich in paratyphoid-A bacilli. These lesions are naturally managed by curetting or resection, and a sinus is left to heal up from the bottom. While we do not know the exact mechanism involved, it is evident that epidermal tissues are now and then transported into the bone cavity, in which locality they may undergo cancerous proliferation after properly healing in. At a recent meeting of the Breslau Surgical Society Hadda reports such a case (*Berliner klinische Wochenschrift*, August 14). He is careful to distinguish it from epithelioma beginning in the epidermis of a bone sinus, which is by no means rare. In the cases under consideration, Hadda says, there is evidently a direct grafting of the epidermal tissues into the bone substance.

Agitation and Its Treatment.

In a paper published in the *Medical Press and Circular*, September 27, Paul Camus says that the causes of agitation are infections, exogenous intoxications, and endogenous intoxications. But all the various causes, infective or toxic, merely bring into relief the hyperexcitability of the individual, whether evident or latent. The states of agitation which occur in the course of general maladies or in that of infections or acute intoxications are nearly always transitory; they require little treatment beyond that of the causal condition; the bath is the best remedy for the agitation of a typhoid patient; as quinine is the sedative, par excellence, in case of paludism. A fever patient affected with agitation, or an alcoholic in delirium tremens, may be treated at home if a degree of relative isolation can be secured in a suitable apartment; not by means of mechanical restraint, but under competent and continuous supervision. When these essential conditions cannot be secured and the agitation continues isolation in an institution becomes necessary. In regard to the treatment of subjects of subacute alcoholism, he advises that they should be placed in rooms brilliantly lighted—during the night as well as by day; this has the effect of diminishing in notable proportion their crepuscular and nocturnal hallucinations, the habitual cause of their agitation and pantophobic seizures. Camus is a believer in the full bath in the treatment of most cases of agitation, while douches are recommended in certain cases. In few cases is he in favor of chemical sedatives for allaying agitation, as they do not attack the cause. Alcohol should be banished from the treatment of delirium tremens, and the use of alcoholic draughts in the early stages of pyrexias and of infections should be proscribed. To sum up, in a word, agitation is only a symptom, in the same sense as fever is a symptom. In each case the treatment to be effective should be aimed at the cause, not an empirical struggle against a simple reactionary manifestation.

The Treatment of Constipation.

The treatment of constipation has been debated at length and frequently in recent years without any certain curative treatment for the condition having been laid down. When it is considered that constipation is often but one symptom of disease, this is not a matter for wonder. There is, however, a form of constipation which lends itself to treatment, the form induced by careless diet or manner of living generally and aggravated by the too free use or abuse of purgatives. In the *Southern California Practitioner* for November Boardman Reed discusses the curative treatment of constipation, and after recommending for the lighter cases exercise, judicious diet, and an abundance of water between meals proceeds to deal with the more stubborn forms. For some such cases a laxative diet and much active exercise are advised, together with the employment of electricity and massage, and insistence is placed upon the great value of vibration applied as follows: vibratory massage of the muscles over the body generally every day for the first ten or fourteen days and later less frequently; stimulation two or three times a week by vibration applied in séances of one minute each over the spaces on either side of the first three lumbar vertebræ between the spinous processes, and the application of the intrarectal vibratode, at the same sitting for from one to one and a half minutes, having the vibrating end of the vibratode at its shortest limit for this part of the treatment. Enemas of olive oil are also recommended. When there is a complicating colitis the author has added to the enema with satisfactory results one-half to one teaspoonful of bismuth subcarbonate well stirred so as to make an emulsion. When spastic constipation is present less exciting measures than electricity and vibratory massage are indicated. Strong acids and the sourer fruits should be omitted from the diet in such cases. When hyperchlorhydria is a symptom it must be cured before any treatment of constipation can be successful. Such patients are usually neurasthenic and need special treatment for that disease.

Ehrlich on 606.

At the recent meeting of the Deutscher Naturforscher und Aerzte, Ehrlich gave a digest of the present status of arsenobenzol therapy (*Deutsche medizinische Wochenschrift,* October 19). From the very beginning of his efforts he investigated the possible unpleasant collateral action of the remedy, and every legitimate announcement which emanated from the experience of others touching upon the hostile activity of the drug has been debited for the time to the account of the latter. Certain curiosities of medical practice have come to light in this endeavor. One case of death supposedly attributable to salvarsan turned out to be a homicide. Some persistent after effects, such as bladder troubles, were due, Ehrlich thinks, to decomposition of the drug from contact with the air. Painful indurations at the puncture, venous thrombosis, and other local sequelæ were due, in his belief, to defective technique in preparing solutions. Much of the headache, vomiting, diarrhea, etc., reported after injections of the remedy might have been due to the bacterial content of the distilled water employed! The auditory and other disturbances of special sense seem to have occurred in subjects predisposed thereto by previous attacks. In fact, few of the untoward symptoms following the use of 606 could justly be attributed to the action of this drug, according to its discoverer. Ehrlich's remedy seems to be gradually establishing itself as a panacea, for he claims that it is essentially curative in syphilis, fowl spirillosis, recurrent fever, yaws, tertian malaria, Aleppo boil, bilharziosis, the pneumonic plague of horses, and African farcy. He failed, however, to mention the alleged curative power of the drug in typhus fever and the bubonic plague, and he went so far as to admit that it has no power over kala azar.

Dr. Doty and Gov. Dix.

An interesting revelation of character is shown in two letters published last week. One, intemperate, abusive, filled with venom, ignoring of facts, and thoroughly illogical, was written, or at least signed, by the Governor of the State of New York, demanding the immediate resignation of the Health Officer of the Port. The other, dignified, logical, temperate, and courteous, was written by the Health Officer of the Port, refusing to resign under the reiteration of these thoroughly disproved accusations. In the words of the declaration of the Academy of Medicine of North Jersey, at a meeting held on Friday evening of last week, the effusion of Governor Dix was "the most brutal and unsubstantiated letter ever written by a State Executive." The only plausible explanation of the Governor's outbreak is found in a news item from Albany, dated December 29: "Governor Dix, who has been suffering from a severe cold for the last few days, was able to be at the Executive Chamber today." The Governor's letter was sent on December 27.

A New Baronet.

The latest-made colleague of Sir William Osler among the British baronets is Sir James Beecham, who made fame and a fortune by the sale of the pills that bear his name. It is not stated whether he was made a near peer because of the therapeutic efficacy of his pills or because he had contributed a tidy fraction of his profits from their sale to the treasury of the Liberal party.

News of the Week.

Smallpox in Various Places.—During the last six weeks there have been eight cases of smallpox in Greater New York, four in Queens, two in Brooklyn, and two in Manhattan. The report made by the State Department of Health on December 23 says that there has been a steady increase in the number of cases of this disease throughout the State. Since December 15 over 10,000 persons have been vaccinated in the five boroughs of the Greater City. In Holyoke, Mass., about sixty people are held in quarantine in two blocks where there are two cases of smallpox. Both the public and parochial schools of the city have been closed and physicians of the Health Board are busy vaccinating. Smallpox has been brought to Philadelphia on an Italian steamship by immigrants, who have been living in a congested negro and Italian settlement in West Philadelphia since December 5. When the existence of the disease was discovered fifty doctors began to work rapidly and vaccinated

about 1,000 people in four hours. The existence of eight cases of smallpox in New York City has alarmed the East Orange Board of Education, which has renewed its insistence that vaccination be enforced among the pupils. This order has brought out the information that only about 8 per cent. of the pupils had been vaccinated successfully.

Typhoid Fever in Ontario.—There is a serious epidemic of typhoid fever in Sarnia, Ont., where 70 cases have been reported up to the present time. The outbreak is attributed to a polluted water supply, as the town obtains water from the St. Clair River, which receives the sewage of Port Huron.

Glanders in Pasadena.—For the past three months glanders has been epidemic in the stables of the Pasadena Ice Company and 30 horses have been shot after having become infected. An employee of the company has been attacked by the malady and is near death, while several others are under suspicion.

Diphtheria in Lenoxdale, Mass.—Because of an epidemic of diphtheria in this village, the Board of Health has ordered that all dogs and cats at large shall be killed and has also forbidden handshaking and kissing. This mandate has been issued because many of the inhabitants are Breton French, an affectionate and demonstrative people, who are given to great gaiety at this season.

Food Poisoning in Berlin.—Between 75 and 100 tramps who had sought shelter in the Municipal Lodging House in Berlin one night last week were taken acutely ill and died. It was thought at first that the deaths were due to ptomaine poisoning from the eating of spoilt smoked herring. A number of those who died and many also of those who are acutely ill are said, however, not to have eaten anything beyond the coffee and bread furnished by the lodging house. Another theory is that the illness was due to the drinking of schnapps adulterated with wood alcohol, but only a few of the dead had had any liquor to drink. An epidemic, said to be of a similar character, is reported in Milan, and Paris sees in these poisonings the beginning of an epidemic of a new plague which it has picturesquely styled the "purple death." Gaffky of the Berlin Institute for Infectious Diseases says the epidemic is one of food poisoning similar to that which was observed and studied by him several years ago in Dantzig.

Insanity on the Increase.—In 372 institutions canvassed by the Census Bureau up to January 1, 1910, there were 187,454 insane patients, or an increase of 37,303 since 1904. During this period the population of the United States increased about 11 per cent. while the number of insane people increased 25 per cent. Massachusetts led the States with 344.6 insane per 100,000 population and New York was a close second with 343.1 per 100,000 persons.

Health of the Canal Zone.—The report of Colonel Gorgas for the month of October states that the total number of deaths from all causes among employees was 46. These were divided as follows: From disease 38, and from violence 8, giving the annual average per thousand of 9.15 and 1.93, respectively. In segregating according to race, the annual average death rate per thousand from disease among employees was: For whites 4.87, and for blacks 10.56, giving a general average for disease of 9.15. For the same month during 1909 the annual average death rate per thousand from disease among whites was 3.10, and blacks 8.56, giving a general average of 7.35; and in 1910 from disease among whites 4.51, and blacks 5.98, giving a general average of 5.58. Among employees during the month the deaths from the principal diseases were as follows: Chronic nephritis, 3; dysentery, clinical, 1; hemoglobinuric fever, 1; lobar pneumonia, 13; malaria, 1; tuberculosis, 6; leaving 13 deaths from all other diseases, and 8 deaths from external violence. The number of deaths from pneumonia have occurred almost exclusively among colored laborers recently brought to the zone from the West Indies, as was the case in 1906 when an epidemic of the disease prevailed. No cases of yellow fever, smallpox, or plague originated on the Isthmus during the month. One case of bubonic plague of the septicemic variety, from Guayaquil, died at Ancon Hospital on October 17. The case was interesting in that it revealed no external lesions of the disease, and was diagnosed at autopsy from smears taken from the spleen and femoral glands.

Death Rates in the States.—A bulletin recently issued from the census office gives the death rates in the registration States for 1909 and 1910 as follows:

	1909	1910		1909	1910
California	13.4	13.5	New Jersey	14.7	15.5
Colorado	14.2	13.8	New York	15.7	16.1
Connecticut	15.0	15.6	North Carolina		18.7
Indiana	12.9	13.5	Ohio	12.9	13.7
Maine	15.6	17.1	Pennsylvania	14.7	15.6
Maryland	15.5	16.0	Rhode Island	15.6	17.1
Massachusetts	13.4	16.1	Utah		10.8
Michigan	13.1	14.1	Vermont	15.7	16.0
Minnesota		10.9	Washington	9.8	10.0
Montana		10.6	Wisconsin	11.8	12.0
New Hampshire	16.9	17.3			

Vegetable Eater Wins Endurance Test.—The Buffum brothers who started to walk from Boson to Los Angeles on July 8, after having been pronounced fit by Dr. Dudley A. Sargent, physical director of Harvard University, arrived at their destination on December 17. The one lived on a meat diet and the other on a vegetable diet during the contest and it was found at the end of the walk that the vegetarian had gained eight pounds and the meat eater three. Neither of them slept under a roof during the trip. Just before finishing their trip they decided to take a side trip into the San Bernardino Mountains and becoming lost were without food for sixty hours. The meat eater was on the point of physical exhaustion after he had gone twenty-four hours without food, while the vegetarian was still in comparatively good condition. Those interested in this experiment feel convinced that vegetables are a far healthier diet, not only for one leading a sedentary life, but for one doing hard physical work, though the results of this experiment are by no means conclusive. The brothers might now reverse their dietary habits and walk back to Boston, by way of a control experiment.

Wants an Interstate Health Train.—Dr. Oscar Dowling, president of the Louisiana State Board of Health, in an address before the Association of Life Insurance Presidents, told of the "health train" which he had sent throughout the State of Louisiana last year and of the interest that it awakened in health reforms, and thought it would be a saving of time, money, and effort to have the main features of an educational campaign such as this put on an interstate basis. One exhibit train with an advance agent would be found adequate. He believed that such a movement would be the greatest ever inaugurated and the most effective for the elimination of sanitary evils, and that an association

of life insurance presidents was eminently fitted to carry on such a work.

The William McKinley Memorial Hospital League announce the opening of a campaign to raise $7,000,000 to equip a hospital in New York City and open air camps at the seaside and in country districts for the treatment of incipient tuberculosis. This campaign was really opened in Connecticut three months ago and the response received was so gratifying that was believed that the fund would be the greatest ever received for the purpose of a memorial. McKinley one cent seals will be put on sale after January 1. Private contributions will also be solicited. The money will be disbursed by a committee of seven persons who have contributed $10,000 or over. The names of twenty-nine governors of states and territories appear on the list of the council of one hundred. George E. Merry is secretary of the league, which has its headquarters at 1 Madison avenue, New York City.

Charitable Bequests.—The will of the late William Pitt Preble, who died recently at New Brighton, N. Y., leaves $5,000 to the Maine General Hospital at Portland. The will of Thomas M. Miller of Pittsburgh gives his home, occupying two city blocks and valued at $1,500,000, to be converted into a hospital to be known as the Woman's Hospital of Pittsburgh. Among the bequests contained in the will of Evelyn S. Ridgeway were the following: Home of St. Giles the Cripple, $2,000; Brooklyn Hospital, $2,000; St. John's Guild, $2,500, the Brooklyn Home for Consumptives and the Brooklyn Nursery and Infants' Hospital, each $1,000. By the will of the late Patrick Gibbons of Philadelphia St. Agnes Hospital and Wills Eye Hospital each receive $500.

Texas State Medical Society Plans Building.—At a meeting of the trustees of the Texas State Medical Society in Forth Worth on December 12 it was decided to inaugurate a movement for the erection of a permanent home for the organization. They are planning for a building to cost $150,000, but leave the question as to the site until the meeting of the society, which will take place in Waco on May 7, 8, and 9, 1912.

Many Abnormal Children in Boston.—Dr. William J. Gallivan, chief of the division of child hygiene of the Boston Board of Health, has announced the results of his first three months' work. Of 42,752 children examined by the school physicians, only 14,957, or 35 per cent., were found to be physically normal, healthy children. The defective children and those below par physically numbered 27,795, or 65 per cent. The defects among this number were as follows: Mental deficiency, 223; defective nasal breathing, 3,562; hypertrophied tonsils, 9,738; defective teeth, 19,518; defective palate, 86; cervical glands, 4,425; pulmonary disease, 456; cardiac disease, 1,129; nervous disease, 213; orthopedic defects, 521; skin disease, 3,509; rickets, 375, and malnutrition, 1,611.

Petition Legislature to Conserve Human Life.—A petition bearing the signatures of more than 75,000 persons will be presented to the Louisiana Legislature at its coming session. This petition urges that the measures endorsed by the Mississippi Medical Association be given favorable consideration and passed. The association asks that a bureau of vital statistics be created, a larger appropriation made for education of the people on sanitation and hygiene, and that a higher educational standard be required of applicants for license to practise medicine in the State. The latter measure contemplates an amendment that will require every applicant for a medical license to first take a standard course of literary study in some reputable college.

Government Condemns Many Tuberculous Cattle.—The United States Bureau of Animal Industry inspected more than 50,000,000 animals during the past year and more than 1,000,000 carcasses or parts thereof were condemned as unfit for food. In most instances tuberculosis was the cause of the condemnation, nearly 47 per cent. of adult cattle condemnations and more than 96 per cent. of those of hogs being due to this disease.

Unlicensed Medical Students Must Not Practise Medicine.—The Louisiana State Board of Medical Examiners has taken a stand against the custom of some medical students of practising during their vacations and even after graduation of beginning practice before obtaining licenses. The board has refused to examine any applicant who has practised without the necessary qualifications after having been notified by the secretary of the board to desist. The board has also passed a resolution making it compulsory for midwives to pass a written examination before being licensed; heretofore only an oral examination has been required.

New York's Foreign Born.—A preliminary statement showing the returns of the thirteenth decennial census taken on April 15, 1910, issued by the Bureau of Census of the Department of Commerce and Labor on December 29, shows that at the census of 1900 the foreign-born white population of New York City was 1,260,918, while in 1910 it had reached a total of 1,926,900, representing an increase during the ten years of 52.7 per cent. Natives of Germany decreased 13.9 per cent. and those of Ireland 8.2 per cent. For the United States as a whole natives of these two countries decreased 11.2 and 16.3 per cent. respectively. Natives of Great Britain, Canada, and Newfoundland have increased 23.2 per cent. during this period, while natives of Sweden, Norway, and Denmark have increased 43.5 per cent. The largest increases were shown for natives of Austria-Hungary, Italy, Russia, and Finland. During the last ten years there has been an increase of 163.7 per cent. in the number of natives of Russia (chiefly Hebrews) and Finland, while there has been an increase of 134.1 per cent. in the number of natives of Italy and an increase of 117.6 per cent. of natives of Austria-Hungary. Natives of Italy and Austria-Hungary now constitute more than one-half the foreign-born population of New York City, as compared with a little more than one-third in 1900. In the United States as a whole the respective percentages are 35.3 for 1910 and 17.2 for 1900.

A Record for Fecundity.—A report comes from Boynton, Okla., that the station master of that town and his wife are the parents of eleven children born in three years. Their eldest child is fourteen years of age and twins are now five years of age. A year after the birth of the twins triplets were born and the following year another set of triplets made their appearance; a year after this five children arrived on the same day, making a record of eleven in three years.

A New Jersey Society Endorses the Quarantine Administration.—The Academy of Medicine of North Jersey at a meeting held in Newark on December 28 protested against the request of Governor Dix for Dr. Alvah H. Doty's resignation as

Health Officer of the Port of New York. At a previous meeting it had been voted to draw up resolutions to send to Governor Dix and to ask that Governor Wilson should use his influence in behalf of Dr. Doty. While these resolutions were pending Governor Dix's letter was made public. The Academy declares this the most brutal and unsubstantiated letter ever written by a State Executive, and urges Dr. Doty not to resign.

Health Inspectors Dropped.—Thirty-four medical inspectors of the New York Health Department have been dropped from the service. The reason given for their dimissal is that the appropriation has been cut down.

The Herter Lectures.—Six lectures on "Immunity" will be given under the Herter Foundation of the University and Bellevue Hospital Medical College, by Prof. L. Hektoen of the University of Chicago. The course will begin on Monday, January 8, at 4 o'clock and continue daily throughout the week, at the same hour, at the Carnegie Laboratory, 338 East 26th street.

Dr. R. G. Broderick, who was formerly Health Officer of San Francisco, has again been appointed to that office in place of Dr. W. F. McNutt, Jr., who has recently retired.

Dr. C. J. Smith of Pendleton, Ore., has been chosen president of the State Board of Health at its annual meeting at Salem.

Dr. Philip F. O'Hanlon of New York City, a coroner's physician, was operated on for an abdominal abscess December 28; his condition is reported as favorable.

Dr. James V. May, Superintendent of the Matteawan State Hospital, has been appointed by Governor Dix president of the State Commission in Lunacy, *vice* Dr. Ferris, who recently resigned. It was at first reported that Max Schlapp of this city had been appointed, but he was unwilling to accept the offer.

Miss Clara Barton, the founder of the American Red Cross Society, celebrated her ninetieth birthday on Christmas at her home, Red Cross, in Glen Echo, Md. She has recently been severely ill, but is now happily restored to health.

Possible Consolidation of Philadelphia Medical Schools.—It is stated unofficially that the Medico-Chirurgical College of Philadelphia is to be consolidated with the University of Pennsylvania. The hospital and college buildings of the former have been condemned to make way for the Parkway. It is suggested that the Medico-Chirurgical College shall become a post-graduate school and that its present faculty and staff of instructors shall be retained.

New York Guardsmen Inoculated Against Typhoid Fever.—Four hundred officers and men of the Seventy-first Regiment, N. G. N. Y., were vaccinated against typhoid fever with serum received from the Surgeon-General's office at Washington, at the Armory, on December 28. All of those who were vaccinated voluntarily submitted to the operation.

Typhoid Inoculation Compulsory in the Navy.—Vaccination against typhoid fever has received the unqualified endorsement of the Navy Department and will be administered at once to all officers and enlisted men under forty-five years of age who have not previously been inoculated. Hereafter all recruits enlisting will be compelled to submit to vaccination against typhoid fever as they now do against smallpox.

Christian Scientists May Practise in the Canal Zone.—President Taft has modified his order relating to the practice of medicine in the Canal Zone, which was interpreted as prohibiting Christian Scientists from attempting cures, by specifically granting this privilege to those whose religion teaches them to treat the sick without the use of drugs, to those who render gratuitous services in cases of emergency, and to those administering the ordinary household remedies.

The McKennan Hospital, a fine brick building costing $10,000, and well equipped in every department, has just been dedicated at Sioux Falls, S. D.

A New Tuberculosis Hospital.—In accordance with the State law Brockton, Mass., is to have a tuberculosis hospital, which will cost about $30,000.

Hospital Collections in London.—While the Saturday and Sunday Association of New York City is striving to raise $200,000 to be divided among 46 institutions, it is interesting to learn that the need of a large hospital fund is better recognized in London than here. In that city the three public collections for hospitals amounted to $1,560,000, the church collections alone aggregating more than $200,000. Here $115,595 was raised last year, of which $30,898 was from church collections.

The Hempstead Hospital Building at Hempstead, L. I., was sold on December 22 for $10,000. The hospital had been given to the town by Mrs. O. H. P. Belmont with the understanding that the people of the town would support it, and was sold because of their failure to meet this requirement.

Work of the Hospital for the Ruptured and Crippled.—This institution has just issued a statement which shows that during the past fifty years 379,999 cripples have been treated. During the year ending September 30 12,604 new patients were treated, and a total number of 43,772 separate treatments were given. There is a school connected with the hospital so that children on their discharge can re-enter their classes in the city schools. The report states that there is a deficit of $4,277 for the year and that the hospital will have to rely upon the generosity of the public to meet this. A plea for funds also comes from the Hospital for Deformities and Joint Diseases, which treated 2,400 cases during the past year as compared with 1,200 during the year 1907 when it was founded, and now has a deficit of $6,000 for the year.

Charitable Bequests.—Alice Stone Blackwell, suffragist and socialist, has given her large old home in Dorchester, Mass., to the New England Women's and Children's Hospital to be used as a convalescent home. The house was formerly the home of Lucy Stone and Henry Blackwell. Under the terms of the will of Emily H. Moir, the Presbyterian Hospital and the New York Eye and Ear Infirmary each receive $20,000. The will of Nathan F. Strauss gives $5,000 to Mount Sinai Hospital and $2,000 to the United Hebrew Charities. The will of Katherine I. D. Harnett bequeaths $10,000 to St. Vincent's Hospital and $5,000 to the New York Society for the Relief of the Ruptured and Crippled. Under the will of Abraham Abrahams the Jewish Hospital of Brooklyn receives $50,000 and the Brooklyn Federation of Jewish Charities $25,000.

The Canadian Public Health Association, which met in Montreal on December 13, 14, and 15, elected the following officers: *President,* Dr. C. A. Hodgetts of Ottawa; *Vice-Presidents,* Dr.

M. M. Seymour of Regina, Dr. J. W. S. McCollough of Toronto, and Dr. E. B. Fisher of Fredericton; *General Secretary*, Major Lorne Drum, M.D. of the Permanent Army Corps of Ottawa; *Treasurer*, G. D. Porter of Toronto. The association will hold its next meeting in Toronto.

A Cure for Mouse Cancer.—Wassermann of Berlin read a paper on December 20 before the Berlin Medical Society in which he related some successful experiments in the treatment of mouse carcinoma by intravenous injections of eosin, selenium, and telluride. In some cases the injections killed the mice, in others the tumor rapidly disappeared after three or four injections. The remedy has not yet been tried on man.

Obituary Notes.—Dr. Arthur Vincent Meigs of Philadelphia, a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1871, died at his home January 1 at the age of 61 years. He was one of the physicians to the Pennsylvania Hospital, a member of the Association of American Physicians, of the American Philosophical Society, formerly president of the College of Physicians, Philadelphia, and a member of many other medical societies.

Dr. Michael J. O'Toole, formerly of Worcester, Mass., died at his home in Clinton, Mass., December 21, at the age of 35 years. He graduated from the Maryland Medical School in 1902.

Dr. Offa L. Shivers, Jr., of Linden, Ala., a graduate of the Vanderbilt University, Medical Department, Nashville, Tenn., in 1901, died December 13 at the age of 35 years.

Dr. Benjamin Perkins of Montgomery, Mo., died at his home December 15 at the age of 82 years.

Dr. Peter D. Leys of Rosyl, Long Island, N. Y., died at his home and was buried December 26. He was 80 years old. When 16 years old he came from Scotland, was shipwrecked and was the only survivor. For some time prior to the shooting of President Lincoln he lived with Wilkes Booth.

Dr. Charlotte Coles Jenkins of New Rochelle died of apoplexy at her home December 25. She was a graduate of the New York Homeopathic College and was 82 years old.

Dr. A. Judson Palmer, a homeopathic physician in Brooklyn, a member of the Brooklyn and New York State Homeopathic Medical Societies, died at his home December 25 at the age of 78 years.

Dr. Augustus V. Hill of Woodcliff-on-Hudson, N. Y., died of apoplexy at his home December 24 at the age of 66 years. He was graduated from the College of Physicians and Surgeons, Columbia University, in 1869.

Dr. Summerfield B. Bond of Baltimore, a graduate of the University of Maryland, School of Medicine, Baltimore, in 1883, chief medical examiner of the relief department, Baltimore & Ohio Railroad, died at his home December 21 at the age of 50 years.

Dr. William H. Ravenscroft of Denver, Col., died of paralysis December 18. He graduated from the Physicians' Medical College, Philadelphia, in 1857. He was 78 years old.

Dr. Isaac J. Lane of North Williamsburgh, Ontario, Canada, a graduate of the Medical Faculty of Queen's University, Kingston, Ont., in 1888, died December 20. He was 55 years old.

Dr. Herman Lewin, a graduate of the New York Eclectic Medical College in 1896, died of heart disease at his home in New York City on December 28. He was official physician to the Letter Carriers' Association of New York City.

Dr. Thomas Cloman Pugh died at his home in Baltimore on December 28, at the age of 74 years. He was graduated from the Medical Department of the University of Pennsylvania in 1859, and served for four years with General Longstreet as a surgeon in the Confederate army.

Dr. Joseph Alberic Genereux of Southbridge, Mass., a graduate of the Medical School of Maine, Portland, in 1886, died December 22. He was 50 years old.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent)

A CRISIS IN THE PROFESSION ON THE INSURANCE BILL—THREATENED DISRUPTION OF THE B. M. A.—MEETINGS IN VARIOUS PLACES TO PROTEST—BRADSHAW LECTURE ON HEREDITY IN DISEASE—UNRECOGNIZED DIPHTHERIA—KING EDWARD'S HOSPITAL FUND—SURGICAL AID—OBITUARY.

London, December 15, 1911.

Yesterday about 2,000 medical men met at Manchester—the North mostly led the way—to protest against the Insurance Bill and the conduct of the B. M. A. They decided to form a National Medical Union, to be an emergency organization to voice the attitude of the profession and to facilitate a unanimous refusal of service under the bill. It is said this union will continue in existence as long as any question remains in dispute, and it was asserted that it would work in concert with members of the B. M. A. But the action of the Council of that body was condemned by every speaker, though several regretted the disorganization of the Association, which they said was the result of its Council, in which their confidence had been shaken. They were determined to wreck the obnoxious piece of legislation, and this they would do by refusing to form a panel. One speaker, who had been one of the deputation to the Chancellor, came forward to defend the "much-maligned body," but was hooted and assailed with the cry of "traitor." Even Sir James Barr, who proposed a vote of thanks to the chairman, when he attempted to offer some excuse for the Council, was told to sit down, but he said if they could wreck the bill he would be pleased. The resolutions, (a) to refuse to form a panel, and (b) to form the Union named above, were carried with only five and six dissentients, respectively, and amid great enthusiasm.

Of course, this meeting is only the culminating point so far of the indignation that has been aroused. The branches of the B. M. A. have been holding meetings in all directions during the week. The Council has sent another circular to show that, though they have not secured their six points, they have done something and mean to do more. Following this they are trying a canvass to get signatures to their declaration and subscribers to the journal. This they manage by getting a member of a branch to call on the men in his district who have not succumbed to the atrocious threat I reported to you last week.

London is to have a mass meeting of the profession on Tuesday next to consider the position. The Manchester resolutions will of course be prominently brought forward. Sir Watson Cheyne will preside and all qualified men are invited to attend.

There seems little doubt that this will be a successful meeting and will act on the Manchester lines, for it is generally said there is no desire to split the B. M. A., but only to condemn the Council and, if possible, to provoke its resignation. One member has already resigned, but what is wanted is its resignation in a body. If they had the courage to do so it would not be surprising for the majority to be reelected, and only the little clique that dominates to be unseated. That would certainly be a reform, but the obnoxious few understand electioneering.

The *Practitioner* is now taking a referendum, asking a plain yes or no to the question, "Are you satisfied that the arrangements made for the profession with regard to the medical service now embodied in the bill would justify you in giving honest and adequate service to the insured?" As an immediate reply is urgently asked, perhaps some result may be announced at the mass meeting in London next Tuesday.

The House of Lords yesterday discussed the medical aspects of the bill; every member had been supplied with amendments desired by the B. M. A. Only amendments proposed by Government were accepted. There was, however, some useful conversation, but its effect was marred by Lord Tenterden, who said the sanatorium benefit was the endowment of research and that was another name for vivisection, and "no good had been obtained from this so-called research; the results had been inaccurate, inconclusive, and contradictory." Viscount Haldane replied that the sanatorium provision had nothing whatever to do with vivisection.

Mr. Clement Lucas, in his Bradshaw lecture at the College of Surgeons on the 6th inst., directed attention to the doctrine of heredity in connection with disease. He mentioned that tuberculosis was universally held to be hereditary until Koch discovered the bacillus, and the lecturer, like most investigators, now rejected the notion of its hereditary nature. The bacillus, he pointed out, is in fact both infectious and inoculable, it has been known for thirty years, and during that period, owing to better sanitation and hygiene, especially better housing and better food, the mortality from tuberculosis has fallen more than half—to ten instead of twenty-five per thousand. He believed that complete segregation would suffice to stamp it out as certainly as muzzling stamped out hydrophobia. Another example of a disease reported as far back as biblical times to be hereditary as well as contagious was leprosy. Hansen discovered the bacillus in 1871 and now it is regarded as an ordinary contagious disease. Thus the belief in its hereditary transmission, which held sway for tens of centuries, has, said the lecturer, been scattered to the winds. He passed on to consider the case of cancer. There had not been the same confidence about this, but the profession had been divided as to whether it was hereditary or not. Paget taught that it was a blood disease which produced local manifestations, but he could not trace a family history in more than one in three of private patients and one in five or six of hospital patients. Dr. Bashford calculates that the chance of death from cancer is one in eleven for men over thirty-five, and one in eight for women of the same age. So great is the frequency of cancer above that age in the general population that on the average a parent or a grandparent would have died from it out of every two families. The lecturer went on to say that he thought we were half way to the discovery of the cause when it was shown that cancer could be inoculated in animals of the same species. If it were admitted that we were dealing with a mildly contagious disease many observations would fall into line. Thus Mr. Lucas could not accept Sir H. Butlin's view as stated in his Bradshaw lecture, and reported in my letter of the 1st inst. To produce a cell which was against its parent and brings about self-destruction was, according to Mr. Lucas, contrary to the laws of Nature, which are directed to safeguarding against danger.

Turning to the nervous system, the lecturer said those who studied mental diseases consider the hereditary tendency indisputable, and remarked on the disastrous results of in-breeding of tainted stocks and suggested that when criminals repeat their kind and recurrent forms of lunacy occur with lucid intervals, during which children are conceived who are sure to be a burden on the State, it may in future be asked whether restriction of liberty in this direction might not be justifiable. He mentioned a case of a father with recurrent lunacy having eight children, of whom five were lunatics. Also a suicidal family, suicide occurring in four generations and all the offspring being lunatics. He would press on the State the adoption of some measure to arrest the increase of lunacy, especially of criminal lunacy.

Unrecognized diphtheria was the subject of a paper at the West London Medico-Chirurgical Society by Dr. Seymour Taylor. He remarked on the difficulty of diagnosis in doubtful cases, especially when no rash or exanthem appeared and the false membrane was absent or else so located as to be invisible. Such cases might at first seem to be only simple sore throat without confirmatory signs of anything more serious, *e.g.* false membrane, enlarged glands, or albuminuria. Illustrative cases were related in which the history of a previous sore throat was obtained only by close inquiry in consequence of paralysis or peripheral neuritis which appeared otherwise inexplicable. Some cases, too, were given showing the great danger of overlooked diphtheria being followed by cardiac paralysis. Dr. Taylor would have a State bacteriologist appointed, one of whose duties would be to examine swabs sent by practitioners. These would settle doubtful cases, but should be taken from the inferior nasal meatus as well as from the fauces. A doubtful case should not be pronounced free from diphtheria until two swabs taken at a week's interval showed complete absence of the bacillus.

Dr. Bernstein said the greatest difficulty was caused by carriers of the organism—often nurses and children, or even doctors. The president, Mr. McAdam Eccles, put some important questions, *viz.*, How soon after possible infection can the bacillus be found? Which is the best area to take a swab from? Are there such organisms as "pseudo-diphtheritic" bacilli? What is the longest time the true *Bacillus diphtheriæ* can remain in the throat of a carrier? Dr. Crookshank said the doctor's first duty, if he suspected diphtheria, was to give antitoxin; then he could go for a swab. He who does this safeguards his patient; he who takes a swab and waits for results only safeguards himself. Several speakers followed, but it cannot be said that the president's significant questions have received satisfactory answers.

On Monday a meeting of King Edward's Hos-

pital Fund was held. The Speaker, who presided, read a message of congratulation from King George in India on the satisfactory result of the year's work. The year's distribution can be increased by £2,500. The report of the committee on the grants recommended to hospitals, convalescent homes, and sanatoria was adopted. The total collection for the year was £157,500. A further sum of £5,000 was voted toward the removal of King's College Hospital, making £42,000 contributed to this object. St. George's Hospital does not apply for a grant, as its managers cannot accept the restriction placed on the amounts which could properly be paid to medical schools for work done for hospitals. The amalgamation of special hospitals is encouraged by an addition to the fund set aside for that purpose.

The Surgical Aid Society's annual meeting was on Monday, when the Lord Mayor presided and announced a substantial reduction in the cost of administration and an increase in the amount given in relief. The number of appliances supplied totaled 30,743. The treasurer, Mr. Watson, in returning thanks, remarked that in 1869, when he first took the office, the income was £1,050; now it had reached £28,000. When he joined appliances were distributed to the cost of £587, but now £24,000 was spent on them.

Sir Joseph Hooker died on Sunday, the 10th inst. His twenty years' directorship of Kew Gardens, to which he succeeded his father, whom he had for the previous ten years assisted in that office, may seem to the general public to obscure his other claims to honor. Not so with those who appreciate science and medicine. For he was a graduate in medicine at the age of 25 at the University of Glasgow. He became surgeon and naturalist to the Antarctic expedition led by Sir James Ross in the *Erebus*. This occupied from 1839 to 1843, and its results were of the highest interest to botanists. They appeared in "Flora Antarctica," "Flora Novæ Zelandiæ," and "Flora Tasmania." In 1847 he went to the Himalayas, and the account of his tropical studies of the geographical distribution of plants secured the enthusiastic approbation of Humboldt, Lyell, Darwin, and in fact all naturalists. Travels in Syria, Palestine, Morocco, and North America gave him results which made Asa Gray say: "No botanist of the present century, perhaps of any time, has seen more of the earth's vegetation under natural conditions." Probably his greatest achievement will be considered his establishment on a rational basis of the science of geographical botany. Of course, academical distinctions were showered upon him. He became president of the Royal Society in 1872. He had been awarded the Royal Medal in 1854, and others were afterwards assigned to him in 1887 and 1892. The Government, always slow to recognize science, made him C. B. in 1869 and K. C. S. I. eight years later, in 1877; but took another twenty years to advance him to the next step of Grand Commander.

Staff Surgeon Norman Ireland Smith, R. N. (retired), died on the 10th inst., after a long illness, aged 44.

Dr. K. M. O'Callaghan, who died yesterday, was formerly a captain in the R. A. M. C. He served with great credit in the Zulu and Burmese wars and had the medal and clasp for each. When serving in India he qualified as military interpreter in Hindustani.

CANADIAN PUBLIC HEALTH ASSOCIATION.

(From Our Special Correspondent.)

THE first meeting of the Canadian Public Health Association was ushered in at Montreal with a great flourish of trumpets. Those responsible for the foundation of the association were determined to leave no stone unturned to render the opening congress a success, doubtless deeming that the first step, after all, does count for a good deal. It may be said emphatically that these efforts achieved their object, for seldom has a meeting of this nature commenced under more favorable auspices. His Royal Highness the Duke of Connaught, Governor-General of Canada, accompanied by the Duchess and Princess Patricia, performed the opening ceremony, with the able assistance of the Hon. R. L. Borden, Premier of the Dominion, and of the Hon. Martin Burrell, Minister of Agriculture. The function, for it may be so termed, as it partook of a social as well as of a national and sanitary character, was held in the Convocation Hall of the Royal Victoria College on the evening of the 13th. The audience was large and representative. Public health officers mingled with personages of note in all branches of science and commerce from every part of the Dominion, and there were perhaps as many women as men present. The chair was taken by the president of the association for the year, Dr. T. W. Starkey, Professor of Hygiene at McGill University. Dr. Starkey gave a brief but fitting address of welcome to the Governor-General and to the Duchess of Connaught and Princess Patricia. In the course of the address he drew attention to a point of singular moment, that the object of the association was not only to interest professional men, but to induce the general public to join the association as well. Dr. Starkey also read the postscript of a letter received from Lord Strathcona in which that veteran philanthropist stated that he had sent a check for $2,500 for the association to use in the way thought best.

The Governor-General delivered a really well-thought-out address dealing with public health matters in which he made some extremely apt allusions. Among other things he emphasized the point made by Dr. Starkey that the association was not founded for medical men alone. His words treating of this phase of the question were so pertinent and apply so well to all countries that they are worthy of being quoted in full. He said that it was an erroneous idea that deep knowledge is necessary for a proper comprehension of preventive medicine. While profound knowledge and tedious research are required by scientists to acquire logical and exact results, the results are comparatively simple of application to our daily life, and in this connection he wished to pay a hearty tribute to the professional men for their willingness at all times to give to the public the benefit of their valuable experience. In the course of his address the speaker made another decided hit and this was in his reference to smallpox, on which subject he is qualified to speak from experience. His Royal Highness referred to some vaccination statistics from India with regard to an epidemic of smallpox which occurred in the district in which he held command and further said that he did not wish to enter into any controversy on vaccination as he knew there was a strong and organized opposition to it, but he would make the simple statement of the fact that in the cemetery

of Gloucester, England, lie the bodies of 270 unvaccinated children who died during the smallpox epidemic sixteen years ago. Only one vaccinated child lost its life in the same epidemic. Mr. Borden said that in the past the matter of public health had been neglected by the Federal Government, but declared that in the future this mistake was to be remedied. To Mr. Burrell, Minister of Agriculture, was left the duty of making the announcement of the evening, one of far-reaching significance. The Minister said, in part: "Health is a very vital matter to our people, far more important than many things we make a fuss about. And, speaking quite unofficially, I would say I believe the time has come when, even if does not demand a portfolio, it should at least have a full-fledged department in the Federal Government." He concluded his address with these wise and weighty words, which might be taken to heart with advantage by peoples and governments of all the civilized world: "Just as soon as sufficient common-sense administrative methods can be arranged, which will cut the overlapping between municipal, provincial, and federal authorities in health matters, you may look for a closer and more cordial cooperation between the various governing bodies." Sir Lomer Gouin, Premier of the Province of Quebec, likewise made an announcement of some importance with relation to the management of public health affairs. He said that the Government of Quebec was anxious to do all possible to aid the work of the association. It had already prepared plans for the division of the province into ten districts, which were to be under the supervision of as many expert hygienists. These were to be chosen by competitive examination from the great English and French universities. Brief addresses were also given by Dr. Guerin, Mayor of Montreal, and by Dr. Montizambert. The latter, as the oldest sanitarian in Canada, having been appointed to an official position by Sir John Macdonald in 1866, gave the history of sanitation in Canada, while moving a vote of thanks to the Duke and Duchess of Connaught.

The serious work of the meeting began on the afternoon of the 13th, and the work was really serious, there having been more than fifty papers contributed. The general sessions and meeting of the sections were held in the Medical Building of McGill University, the use of which was granted to the association by the faculty of the university. It is needless to say that no more suitable place for such a gathering could have been found. At the first general session several good papers were read. Col. G. C. Jones, M.D., M.R.C.C., Ottawa, Director General Medical Services, Department Militia and Defence, read a paper on "Military Aspects of Sanitation." It was pointed out in the paper that, although Canada was regarded as the reverse of a military nation, yet it must be borne in mind that a form of conscription was in force and therefore military sanitation was a question of considerable importance. Dr. P. H. Bryce read a paper on "Conservation of Food by Cold." The paper read by Dr. J. D. Pagé, Quebec, was of quite as much interest to sanatarians of the United States as of the Dominion. The question of ship surgeons on immigrant ships was discussed by a medical inspector at the Port of Quebec. The paper dealt with the necessity for a stricter and more efficient examination by ship surgeons of immigrants to Canada than is at present the case. During the months of the year when navigation to Canada via the St. Lawrence route is open between 2,000 and 3,000 persons are examined at the Port of Quebec every day, and the entire responsibility of deciding upon the fitness of immigrants to enter Canada rests on the shoulders of the medical inspectors of the port. This is a heavy responsibility and a state of affairs which, in the opinion of Dr. Pagé, should not exist. He draws attention to the somewhat notorious fact that medical examination on shipboard is more or less perfunctory. The regulations impose on ship surgeons the duty of careful examination of immigrants, but these regulations are more honored in the breach than in the observance, and thus, as said before, the duties of the port inspectors are rendered more onerous than they should be. It is obvious that no one has more favorable opportunities for judging as to whether an immigrant is mentally and physically fit than is the ship surgeon, and it would manifestly be to the best interests of all concerned if he fulfilled his obligations. According to Dr. Pagé, and his reasoning seems sound, the chief cause of ship surgeons evading their duties is that they do not take them seriously. They are for the most part young men who take these positions merely for a change and a cheap trip. Of course, however, the fault lies in the system. The steamship companies are really to blame for the situation in that they do not pay sufficient remuneration to make it worth the while of skilled, trained men to become ship surgeons. The pay is paltry and the result is that the work, as is always the case in such instances, is not properly performed. Dr. Pagé said that he had spoken to several shipowners on the subject, and their answers had invariably been that so long as they could obtain an almost unlimited supply of ship surgeons at a small salary, they saw no reason why they should change their methods, thus once again seeming to prove the truth of the adage that "corporations have no consciences." The speaker said he thought that means should be devised to impel shipowners to pay their medical men a fair wage so that they might attract to the immigrant ship service skilled and trained men in place of men who merely look upon such employment as *faute de mieux*. Dr. Pagé suggests that $1,000 a year would be a fair initial salary for a ship surgeon.

STEVENSON AT SARANAC.

To the Editor of the Medical Record:

Sir:—Your issue of December 16, page 1231, contains a note about Robert Louis Stevenson at Saranac Lake. The writer speaks of the morbid touches and ghastly fancies peculiar to many of Stevenson's stories, saying that "the reason may lie in those tuberculous toxins which were coursing in his blood." The writer of the article does not refer to the well-authenticated fact that Stevenson got many of his ideas for stories from his dreams, and, in fact, systematically recorded in note-books the fantastic images that his nightly slumbers provided. This fact, if mentioned, would have carried the writer's suggestion far toward probability.

Contagious Affections of the Skin in Preparatory Schools and Colleges. J. T. Bowen.
The Diagnostic Importance of Hemoptysis. W. B. Bartlett.
The Comparative Toxicity of Various Alcoholic Beverages. J. Friedenwald.
Tissue Necrosis Following Injections of Salvarsan. R. L. Sutton.
A Report of Nine Cases of Ocular Syphilis Treated by Salvarsan. F. E. Cheney.

Contagious Affections of the Skin in Preparatory Schools and Colleges.—J. T. Bowen describes the following as of common occurrence in preparatory schools and among younger members of colleges: Impetigo contagiosa, scabies, ringworm, marginated dermatitis of the thighs and axillæ, alopecia areata, and verrucæ. The author notes that there is much evidence in support of the theory of these who believe that at least some of the cases of alopecia areata are communicable. In an asylum containing sixty-nine girls sixty-three cases of this disease broke out during a period of four months. In verrucæ the author believes that there is an infective agent present, as well as in most other varieties of papilloma.

Diagnostic Importance of Hemoptysis.—W. B. Bartlett concludes from his study of the subject that bleeding from the upper air passages must be ruled out by careful inspection and history. Hemoptysis may occur in certain constitutional or blood diseases as merely another manifestation of the general tendency to bleed. Hemoptysis frequently occurs in broken compensation in heart disease and may occur in mitral stenosis as the only symptom of failing compensation. In such cases tuberculosis is frequently suspected; it is, however, rarely found. Ninety per cent. of all hemoptyses are due to pulmonary tuberculosis. As a rule definite signs and symptoms are present. Not uncommonly, however, signs and symptoms do not develop for months or even years. Hemoptysis may occur in any ulcerating or eroding pulmonary disease. It should, therefore, be expected in abscess, gangrene, bronchiectasis, or pulmonary cirrhosis. In such cases careful study of the signs and symptoms and frequent examinations of the sputum will usually suffice to rule out tuberculosis. Hemoptysis in pneumonia, bronchitis, asthma, or following trauma should lead to the suspicion of an underlying tuberculous process. It is very doubtful if vicarious menstruation or hysteria can produce hemoptysis in normal lungs. Hemoptysis occurring without warning in young and healthy adults and passing off without the development of further signs or symptoms of tuberculosis is probably of tuberculous origin and should be so treated. Bronchopulmonary hemorrhage without definite symptoms or signs of cardiac or ulcerative pulmonary disease is due in nearly every instance to tuberculous infection, which is merely another way of saying that hemoptysis should be considered as due to pulmonary tuberculosis unless proved to be due to some other cause.

Comparative Toxicity of Alcoholic Beverages.—By J. Friedenwald. (See MEDICAL RECORD, Vol. 79, page 1073.)

Tissue Necrosis Following Injections of Salvarsan.—R. L. Sutton believes that the intramuscular injection, although slightly painful, is the safest and best method of administering this drug. Abscesses result from one of three causes: improper preparation of the solution or suspension employed, insufficiently deep injection of the drug, and bacterial contamination. Examination by the author of the walls of one of the cavities showed an increase of fibrous tissue, with complete blocking of the smaller vessels and lymphatics by minute particles of salvarsan. Numerous small masses of the substance were also found in pocket-like cavities distributed through the section. There were degenerative changes, with decrease in amount, of both connective and elastic tissue. In the immediate vicinity of the lesion evidence of inflammation was almost entirely lacking, and round cell infiltration was conspicuous by its absence. In this instance it is probable that the drug, which had been employed in supposedly alkaline solution, had not been completely dissolved. In treating these lesions the author has found it best to dissect or curette out the lining of mummified tissue and allow the cavities to fill up by granulation. Balsam of Peru, with an occasional application of copper sulphate or powdered alum, is of value. When the healing process is well established recourse may be had to an 8 per cent. scarlet R ointment.

Salvarsan in Ocular Syphilis.—F. E. Cheney reports two cases of acute iritis with condyloma, in which there were a rapid subsidence of the inflammatory symptoms and a disappearance of the condyloma following the injection of salvarsan. This treatment caused the entire disappearance of the inflammatory symptoms in eleven days in a case of chronic general uveitis. In a fourth case, one of a low form of long-continued general uveitis, there was no immediate result following the injection of salvarsan. In four out of five cases of interstitial keratitis treated by means of salvarsan there was a rapid disappearance of circumcorneal injection, of photophobia, and of lacrymation. In three cases there was no exceptional rapidity in the clearing of the corneal infiltration.

Diagnosis. A. M. Corwin.

Sterility in Women.—E. McDonald notes that 10 per cent. of married women are sterile. Rich diet, indolence, and lack of exercise have a distinct effect in increasing sterility. The husband is responsible for the sterility in a quarter or more of all cases. Among the causes of sterility in women are imperforate hymen and vaginismus, infantilism of the genitalia; gonococcus infection; ovarian disease; misplacements of the uterus; perineal laceration; operations, chiefly curettage; fibroids; systemic diseases such as anemia, diabetes, syphilis, and obesity; certain drugs, such as opium, and certain occupations, such as working in tobacco.

Phenol Treatment of Tetanus.—P. Kintzing reports seven cases of tetanus successfully treated by means of the method introduced in 1892 by Baccelli, namely, the hypodermic injection of phenol. The author used a solution of pure phenol of 10 per cent. strength, made by dissolving the deliquesced crystals in sterile water. This solution was then diluted to suit the case, generally to thirty or forty minims and administered by hypodermic injections deep into the muscles; the dose being repeated at intervals of three hours in the beginning, increasing the interval as improvement manifested itself. The full adult dose employed was ten drops of this 10 per cent. solution equaling practically one grain of pure crystalline phenol. As a precaution against soreness or suppuration the author has sometimes diluted with sterile water half the stated amount, five drops, to the capacity of a twenty-five or thirty-minim syringe, injected this into one buttock, following immediately with the remainder of the dose into the opposite buttock; the succeeding injection may be made into the deltoids or the pectoral muscles, if deemed advisable. The author regards the antitoxin treatment of tetanus as far from ideal and in his own experience disappointing.

The Origin of Life.—H. C. Bastian refers to his experiments, by means of which he believes he has created living microorganisms from sterile solutions of inorganic salts, chiefly sodium silicate.

Operative Treatment of Fractures.—L. P. Magruder states that operation is indicated in the closed fracture of wide displacement and when correct apposition is otherwise impossible, provided hospital facilities can be obtained. Operation is indicated in articular fractures when ankylosis threatens, and the best results are obtained after exact coaptation and suturing of the fragments. Massage, followed by early passive motion, gradually made active, should be the practice. When operation is indicated at all, the earliest operation is the best. The operative treatment of open fractures is that which most nearly reduces them to the type of the closed fracture, except as to drainage. Gunshot fractures should be treated like fractures of the open type in contact with street dust. That is to say, in addition to the usual treatment one should administer, as a wise precautionary measure, antitetanic serum. In all cases the most exact coaptation and retention of the fragments give the most gratifying results. The ideal suture is one strong enough to hold until union begins and then admits of its own absorption. The nearest approach to this is the sixty-day chromic catgut, which is unsafe and unsatisfactory in the presence of tension. The most trustworthy metal suture is the tinned steeled annealed wire. Wiring is the best operative method of treatment.

Evolution of the Operative Table.—F. Hartley and F. W. Murray state that, with the exception of Brown's goiter attachment, they are unable to find among the modifications, adaptations, and additions of the table devised by Bainbridge a single one which was not a part of their table in 1908.

Interesting Obstetrical Cases.—S. J. Seadron presents the histories of the following cases: accidental concealed hemorrhage; large hematoma vulvæ complicating labor, and a second cesarean section for threatened rupture of the uterus.

Hepatoptosis.—A. F. R. Andresen states that this condition, which is frequently associated with ptosis of the other viscera, is more common than is generally supposed. It is a congenital anomaly, and is a potent cause of neurasthenia. Treatment consists of improving the general condition of the patient and the strength of the abdominal musculature.

Treatment of Diphtheria Carriers.—H. Page reports the case of a child in which, following an attack of diphtheria, the persistence of Klebs-Löffler bacilli in the throat was treated successfully by swabbing the latter with pure cultures of *Staphylococcus pyogenes aureus*.

A Symbol of Diagnosis.—V. M. Corwin states that the human hand may be made to symbolize the art of diagnosis. The entire hand, guided by enthusiasm, industry, trained senses, experience, judgment, and reasoning, grasps the entire clinical situation with the aid of the five fingers, family history, personal history, laboratory findings, subjective examination, and objective examination.

Journal of the American Medical Association.

December 23, 1911.

Drugs and the Nervous Mechanism of the Heart.—R. L. Wilbur states that the rôle of the serous surfaces of the heart in drug effects needs more consideration. Strophanthin acts largely on the nervous mechanism of the heart, perhaps partly through its stimulation of the sensory nerve-endings of the endocardium. The effect of strophanthin on conduction within the terrapin heart can at times be overcome by strychnine. This conduction is probably along nervous paths. The preliminary administration of strychnine enhances the early stimulating effects of strophanthin. The author concludes that the relation of these drugs should be further studied clinically, as should the use of strychnine alone or in conjunction with atropine in partial heart-block.

Two Rubber Drainage Tubes in Abdominal Surgery.—By P. A. Harris. (See MEDICAL RECORD, July 8, 1911, page 105.)

Parturition in a Patient with Imperforate Anus.—O. Smiley reports the case of a primipara aged 27 in whom the anal orifice was on the posterior wall of the vagina two inches above the introitus. The patient was delivered of a nine-and-one-half pound infant with the aid of forceps.

Thigh Support for Kidney Operations.—D. N. Eisendrath has devised an apparatus for keeping both thighs flexed during a kidney operation by supporting the upper thigh on a wide, well-padded metal band.

Vaginal Speculum.—D. H. Palmer describes a self-retaining vaginal speculum which he has found of value as an aid in immediate repair of the perineum. The vaginal walls are held apart by two lateral blades which are controlled by threaded screws.

Uterine Fibroids.—By W. B. Dorset. See MEDICAL RECORD, July 8, 1911, page 104.)

Febrile Reactions After Salvarsan.—H. F. Swift and A. W. M. Ellis state that whatever may be the true explanation of the febrile reaction, the fact remains that the preparation of salvarsan with freshly distilled and sterilized water eliminates practically all unfavorable toxic symptoms. With the toxic action of salvarsan eliminated, repeated doses can be safely given and, no doubt, more effectual results will follow its more thorough application.

Arthritic Muscular Atrophy.—C. L. Allen finds that the evidence does not favor the idea of a unique cause as effective in all cases of arthritic muscular atrophy, but would indicate that the atrophy is the product of a number of different factors which may be responsible to different degrees in different cases.

Sanitation of the Great Lakes.—G. E. Fell calls attention to the dangers associated with pollution of the water of the great lakes, which dangers call for immediate consideration at the hands of an authoritatively constituted central medical body in respect to the control and the betterment of conditions.

Immuno-Diagnostics in Internal Medicine.—By W. J. Butler. (See MEDICAL RECORD, July 1, 1911, page 48.)

Treatment of Gastric Neurosis.—By C. L. Greene. (See MEDICAL RECORD, July 8, 1911, page 93.)

Complement in Human Serum.—C. H. Bailey concludes from his investigations that human complement capable of acting with human amboceptor to produce hemolysis is not destroyed by a temperature of 41° C. for thirty

minutes. Freshly drawn human blood contains a considerable amount of complement capable of acting with human hemolytic amboceptor, and such complement is not destroyed by heating at 41° C. for thirty minutes. The blood of a patient with a temperature of 40° C. contains complement capable of acting with human hemolytic amboceptor. Complement does not necessarily disappear from human sera in seventy-two hours after withdrawal from the body.

Human Rabies.—H. Hanson reports a case of this condition with autopsy findings and reviews the various features of the disease.

Artificial Infant Feeding.—By F. C. Neff. (See MEDICAL RECORD, July 8, 1911, page 107.)

Verruca Peruana.—S. T. Darling states that this disease is interesting from several points of view: to the parasitologist on account of the peculiar bodies in the erythrocytes, and on account of its probable transmission by ticks or other suctorial invertebrates having a peculiar geographical and altitudinal distribution; to the hematologist, on account of the remarkable blood picture in the malignant form of the disease, there being a profound anemia; to the physician and quarantine officer, from the fact that the disease is rife in certain districts in Peru, where Americans have commercial interests and where American physicians and engineers, bridge builders, and other mechanics have occasion to pass through or work within infected zones. Convalescents occasionally return to the United States with some evidences of the disease still present on their persons. Verruca peruana is an infectious disease in which a fever of irregular type, associated with more or less severe anemia, is followed by a wart-like eruption of the skin, and sometimes of the mucous or serous membrane.

Verruca Peruana.—By H. A. Giltner. (See MEDICAL RECORD, July 1, 1911, page 46.)

Pelvic Disease and Exophthalmic Goiter.—By V. E. Hertzler. (See MEDICAL RECORD, July 1, 1911, page 51.)

Pre-Neurasthenic and Pre-Insane Condition in the Young.—R. Moore notes that the neurasthenic adult is the result of a neurasthenic child plus exhausting illness. Natural juvenile neurasthenia is clear cut. Its symptoms are as follows: On the physical side a general droopiness, poor standing balance, diminished expression in face, fullness under eyes indicating fatigue, other fatigue signs, as when arms are extended one is lower than the other and thumbs droop, twitching fingers, abdomen thrown forward when trying to stand erect; on the nerve side, marked inability to accomplish, due to mental, not physical, fatigue, a mental apathy more apparent than real, abnormal sensibility to external impressions, such as sudden noises, etc. The pre-emotional type shades into and is often combined with the neurasthenic type. Children of the latter type are usually well formed physically, while those of the pre-emotional type may show various physical stigmata of degeneracy. The key to the pre-neurasthenic type is fatigue. The key to the pre-emotional type is instability. The key to the pre-dement type is internal strife.

Acute Ascending Paralysis.—C. W. Hitchcock reports a case of this condition occurring in a soldier 24 years old. There were no true atrophy and but slight sensory phenomena and the case resembled in many respects the fatal case described by Landry in 1850. The author suggests that many of the cases which have served to confuse the pathology of Landry's paralysis are only cases of acute poliomyelitis, in which the spinal cords, could they be examined, would reveal lesions of a distinctly inflammatory character, presenting quite a different pathological picture from that in which Landry was unable to demonstrate any definite changes.

Multiple Prostatic Calculi.—W. D. Webb reports a case in which a mass composed of thirteen hard, faceted stones consisting of phosphates was found in the site of an old prostate which had been removed years before.

Intraabdomino-Pelvic Pressure in Man. R. H. Paramore.
A Year's Work in Abdominal and Pelvic Surgery in the Royal Victoria Infirmary, Newcastle-upon-Tyne, and in a Private Hospital during 1910. R. Morison.
Venereal Disease: Its Present and Future. D. White and C. H. Melville.
Case of Rapid Involution of a Uterine Fibromyoma after Parturition. R. L. E. Downer.
The Use of Calcium Salts as a Prophylactic Against Serum Rashes. M. A. Cassidy.
A Diplococcus from the Urino-Genital Tract. L. S. Dudgeon.
Splenomegalic Polycythemia with Cyanosis (Osler's Disease or *Maladie de Vaquez*). E. Clark-Jones.
Ovarian Cystoma of Unusual Size Complicated with Ventral Hernia and Ascites. H. Macnaughton-Jones.

Intraabdomino-Pelvic Pressure.—R. H. Paramore states that the combined effect of the abdominal wall and thoracic diaphragm is to cause a general compression of the abdominal viscera. These have definite shapes; even the hollow intestinal tract, as sections of the frozen body show, and the facets on the surfaces of the more solid organs are clear evidence of how they all are compressed against each other and the enclosing walls during life, demonstrating, too, how by opposing each other and these walls they are maintained in place and are not suspended in the normal by any ligament. The pressure so caused in the large and extensive abdomen is propagated to the pelvis, which in its phylogeny, and indeed ontogeny, has reacted by an adaptation of its structure to successfully withstand it. The intraabdomino-pelvic pressure, even that maintained during posture and rest, subserves most important circulatory functions. It not only quickens the whole circulation, but renders the blood richer and purer in a shorter time; and this is the reason of its far-reaching effects on general metabolism. By maintaining a high aortic pressure it lays the foundation for an efficient cerebral circulation so important to man; it is, indeed, by its means that man has been able to evolve and is able to maintain a vigorous and strenuous life, both physical and mental, in spite of his erect carriage and the elevated position of his brain.

A Year's Work in Abdominal and Pelvic Surgery.—R. Morison finds that surgical results are not influenced by the costly and elaborate arrangements of the modern hospital, but that they depend upon strenuous personal endeavor on the part of everyone concerned to carry out the simple essential requirements of present-day surgery.

Venereal Disease.—D. White and C. H. Melville state that the present time is favorable for the commencement of a campaign against venereal disorders. Gonorrhea can be cured in its early stages, and its present incidence might be enormously diminished; against syphilis there is a specific, by means of which, rightly used, this disease might in a short time be eliminated. If full advantage were taken of these facts the economic and the moral gain to the community, resulting from the diminution of disease, would quickly, amply, and repeatedly repay the cost of such an effort, for which the means are at hand and the time is ripe.

Rapid Involution of Uterine Fibroid.—R. L. E. Downer reports the case of a fibroid tumor of the uterus, of the size of a cricket ball, which entirely disappeared in the course of two months during the process of involution of the uterus after parturition.

Use of Calcium Salts Against Serum Sickness.—M. A. Cassidy finds that, in cases treated with diphtheria antitoxin, the administration of calcium salts for the purpose of preventing or mitigating antitoxin rashes has been found by actual trial to favor the occurrence and duration of these rashes.

Diplococcus from the Genitourinary Tract.—L. S. Dudgeon and P. N. Panton describe a diplococcus which

they have isolated from different parts of the genitourinary tract. In its staining properties, and its morphological appearances, and in the nature of its colonies on agar, this organism closely resembles the pneumococcus, yet in every other respect the two bacteria are widely different. The diagnosis of a pneumococcal infection can only be made after full cultural and other investigations, yet the frequency with which the pneumococcus has been reported from the urine and from vaginal discharges depends upon the mistaken identity of that organism with the one which the authors describe; in fact, there is evidence that this mistake does occur. The organism is one not infrequently met with, and may be unaccompanied by any evidence of disease. In a certain proportion of cases, however, it is associated with the ordinary phenomena of inflammation and may be the sole organism detected. The cocci appears to have little or no pathogenic action on mice or rabbits.

Splenomegalic Polycythemia with Cyanosis.—L. Clark-Jones reports a case of this condition which is also known as Osler's disease or *maladie de Vaquez*.

Ovarian Cystoma.—H. Macnaughton-Jones reports a case of ovarian cyst of unusual size complicated with ventral hernia and ascites in a patient aged 67 years.

British Medical Journal.

Bier's Hyperemic Treatment. H. E. Waterhouse.
Leprosy: A New View of Its Bacteriology and Treatment. Capt. T. S. B. Williams.
A Remarkable Daily Variation in Leucocytes in Several Diseases. Malarial Fever, Hodgkin's Disease, Cancer. D. Thomson.
The Dangers of Saline Injections. E. C. Hort and W. J. Penfold.
A Report of Six Cases of Arsenical Poisoning Caused by Fumes from a Coke Stove. J. G. Taylor and K. V. Trubshaw.
A Note on Paroxysmal Attacks of Dyspnea, Occurring at Night in Heart Disease. H. Barber.

Bier's Hyperemic Treatment.—H. E. Waterhouse lays down the following axioms which must underlie the successful carrying out of this treatment. One should be careful that throughout the whole course of the treatment the blood continues to circulate freely throughout the part subject to treatment. One should be assured that the treatment be painless, or at least that it mitigate any already existing pain. The chief aims of Bier's treatment are the arrest of an infective process, or at least its mitigation, the prevention of suppuration in many cases in which this is threatened; the relief from, or at least the mitigation of, pain; the avoidance of operative treatment in many cases, or, where this is not possible, the employment of a less severe and less mutilating operation than would otherwise be necessary—thus the required incisions may be few and small instead of many and extensive; the saving of time owing to hastening the eliminating processes in cases in which suppuration and necrosis are unavoidable, as in carbuncle; the increase in the antimicrobic power of the circulating blood, due in large degree to the greater quantity of blood circulating in the diseased part, and the stimulation of the process of repair, as in cases of delayed union of fractures. Elastic constriction gives rise to a purely venous, that is a passive, hyperemia. Suction by means of cupping glasses produces a hyperemia which is at first arterial or active, but soon become venous or passive. Hot air occasions a hyperemia which is purely arterial, that is, an active hyperemia. In every case in which pus is present it is absolutely necessary that, prior to the commencement of Bier's treatment, the pus be evacuated.

Leprosy.—T. S. B. Williams advances the view that the lepra parasite is not an acid-fast bacillus belonging to the fission fungi, but that it is a very pleomorphic streptothrix, which, in addition to changes in form, exhibits marked changes in its staining reactions in regard to the quality known as "acid-fastness." The author's prolonged investigation has shown that it is possible, with a vaccine made from the acid-fast phase of the organism, to influence the disease materially, and to cause, in many cases, marked retrogression, and even complete disappearance of the outward signs of the disease.

Daily Variation in Leucocytes in Disease.—D. Thompson has observed in malaria that the leucocytes change very markedly in numbers and in variety, according to the stage of development of the malarial parasites and also according to the number of parasites present in the blood. During the sporulation of the parasites the percentage of mononucleated leucocytes falls markedly, and when many leucocytes are present the total leucocyte count is also low. When the parasites are very numerous there tends to be a constant leucopenia, but as the numbers of parasites become reduced the leucocytes increase, and finally the marked periodic leucocytoses occur when the parasites are too few to be detected. The author advances the view that this latter phenomenon is due to the sporulation of small numbers of parasites. It has been suggested that these leucocytic variations might be of great value as a diagnostic sign of latent malaria. In septic diseases with suppuration it was found that the number of leucocytes remained more or less constantly high, with a tendency to be more numerous during the intervals between the swinging temperatures. In Hodgkin's disease the leucocytic phenomena are very similar to those found in malarial fever, with the difference that in the latter the mononuclear percentage does not remain as uniformly high as in the former. This suggests that Hodgkin's disease may be due to some protozoal parasite having a definite periodic development. In a case of cancer studied by the author there was a marked daily rise and fall in the number of leucocytes very similar to that of Hodgkin's disease, which similarly suggested the possibility of the presence of a protozoal parasite.

Dangers of Saline Injections.—E. C. Hort and W. J. Penfold conclude that saline injections as at present administered are by no means free from risk, especially when they are large. The cause of the toxicity of distilled water that is allowed to stand in sealed sterile vessels is not yet explained. Neither centrifuging, filtration through cotton-wool or bacterial filters, nor boiling is sufficient to prevent the fever that follows saline injections. Distillation in a sterile Jena retort of all water used in the preparation of saline solutions, followed by immediate injection, is at present the only reliable method of ensuring that no fever follows the injections.

Arsenical Poisoning by Fumes from Coke Stove.—J. G. Taylor and K. V. Trubshaw report several cases of poisoning from coke fumes escaping into the air of a room. The poisoning was proved to be arsenical by the detection of arsenic in the urine of the two worst cases.

Paroxysmal Cardiac Dyspnea.—H. Barber has met with four cases in which very definite paroxysmal attacks of dyspnea came on suddenly in the middle of the night as one of the earliest symptoms of a diseased heart.

Hyperglobulia in Congenital Heart Disease.—W. Bie and W. Moor report a case of pulmonary stenosis and patent foramen ovale in which hyperglobulia was present. This is attributed to the increased formation of erythrocytes resulting from the stimulus of oxygen-deficiency on the erythroblastic organs.—*Deutsches Archiv für klinische Medizin.*

Opsonic Power of the Blood in Diabetes.—P. Sisto states that this is diminished with reference to a variety of microorganisms, chiefly staphylococci, streptococci, and tubercle bacilli, and that this diminution is present irrespective of the presence or absence of complications caused by these bacteria. The opsonic index has no quantitative relationship to the degree of glycosuria or of acidosis.—*Clinica Medica Italiana.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

PERSONAL HISTORY.

Rheumatism.—When there is a history of acute articular rheumatism, it is most important, on account of the well-known tendency of this disease to recur under ordinary exciting conditions and to affect the heart, for the examiner to be careful in giving the number of attacks, the date, duration, and severity of each attack, the name of the joints involved, and a full account of any cardiac complications. The consideration of these facts fairly well establishes the individual tendency to recurrence and liability to future trouble, and as applicants who have had acute inflammatory rheumatism are classified into those to whom insurance may be issued at the ordinary rates or on some form of endowment, or who should be postponed or declined, no conclusion can be reached at the home office until these data are supplied.

It should always be kept in mind that the heart may have been involved during an attack without leaving much or any evidence, and a special effort should be made to find out if any cardiac complication did occur, as the applicant in such cases is not acceptable until at least five years have elapsed since the attack.

The sequelae of acute articular rheumatism which tend to shorten life usually show the signs of their sinister work when the subject has passed the age of fifty, and an endowment policy may be written therefore in some cases when it would not be advisable to issue one at ordinary rates and the case is not bad enough for postponement. The most general practice, perhaps, in rating these cases is to give a policy at ordinary rates where there has been one atack not too recently and an endowment policy when there have been two attacks, the last one at least a year before the date of the application. Three attacks indicate so strong a predisposition to recurrence that it is advisable to reject unless a long period of time has elapsed since the last one.

The endowment policy will be referred to several times in these lines when discussing rheumatism, gout, syphilis and overweights, and it will not be out of the way to give a brief explanation of the value of this contract under certain circumstances. The evil effects of the conditions just named usually begin when the subjects have passed the age of fifty or sixty, as the case may be—in other words, as a class these applicants do not live up to the regular expectancy. If, then, a policy can be written which will completely mature at about a certain age and not call for any further obligations on the part of the company, applicants may be accepted on this plan who would otherwise have to be rejected. The endowment policy fulfills this requirement, for by the terms of this contract the transaction is absolutely completed at the end of a stated number of years on terms fully understood by and satisfactory to both the policy-holder and the company. It is the termination of the contract at a given age rather than the increased premium which makes this form of policy so appropriate for certain cases.

Chronic rheumatism develops more commonly in adult life and a reliable history is therefore more easily obtained, and in addition to this there is apt to be some indication of the disorder at the time of examination. Patients do have respites from the effects of this disease, however, or they may have only some remaining pain or stiffness which has not affected the general health. In any event a complete history should be furnished, as applicants who are or have been afflicted with this trouble, if insurable at all, are only entitled to some form of endowment policy.

An occasional twinge in a joint without any previous swelling, inflammation or actual severe pain in the part is not worth mentioning.

Muscular rheumatism or lumbago is of no importance unless it has become chronic, in which case declination or an endowment policy is in order. A history of muscular rheumatism or lumbago should always be reported and it should be specifically stated whether or not any joints were affected in order to avoid confusion at the home office.

Gout.—Rejection is called for in a high percentage of the cases in which there is a history of gout. Before intelligent action can be taken at the home office, full details will be required, especially as to the number of attacks, the date, duration and severity of each attack and the names of the joints affected. Furthermore, the medical officers will want to be informed whether there have been any gouty symptoms between the acute attacks and, if so, their nature. Still further, they should know whether the applicant has been the subject of renal colic, albuminuria or glycosuria, as any one of these conditions as a complication denotes that there is some disease of the kidneys or metabolism.

Whenever a history of gout is acknowledged the urine and blood vessels should be examined with unusual care, and the hands and ears inspected for the presence of tophi. It is advisable to take the same precautions when an inherited diathesis is evident, though there has not been a typical attack of gout, as the inheritance sometimes manifests itself in such individuals by degeneration of the heart, blood vessels, and kidneys and may provoke changes in the nervous system.

In order that the examiner may fully understand the importance of all these requirements, it may be added that the presumption is against the acceptance of an applicant who has had gout. Exceptions may be made when the family inclination to gout is not too marked, when the disease did not assert itself until after the applicant was thirty years of age, when there has not been more than two attacks, both of which were mild in character, and when the attack, or the last one if there were two, occurred at least five years previously, when there is an absence of renal colic, albuminuria, and glycosuria in the personal history, and when the habits of the applicant are abstemious both as to drinking and eating.

It should never be forgotten when considering the question of gout, and this will explain the reluctance of life insurance companies to insure those subject to this disease, that there is a strong liability in these cases to the diseases of the blood vessels and kidneys which have become so prominent during the last 10 or 15 years as agents for shortening life. The bad results from the changes in these organs as well as in the nervous system are not apt to appear until after fifty years of age when the gouty attacks have been few in number and mild in character, and in these cases an endowment

policy may be granted occasionally for the reason fully described in the explanation of the advantage gained in issuing endowment policies in the section on rheumatism.

Pleurisy and Tuberculosis.—H. Koster writes an extremely instructive paper on the incidence of tuberculosis after pleurisy with effusion and after dry pleurisy. He mentions first that Allard has recently examined the records of 200 patients who have gone through a dry or a wet pleurisy, without an evident etiological factor, fifteen or more years before Allard's study. Of these 200 persons 180 had an effusion and 20 dry pleurisy. Of the 180, 81 were found living and in good health, 24 were surely tuberculous, 57 had died of tuberculosis in the meantime, and 18 died of other affections. Of the 20 persons with dry pleurisy 6 were found living and well, 4 were tuberculous, 1 had died of tuberculosis, and 6 had died of other diseases.

Koster's material, which he compares with Allard's, was still more abundant. His cases date from the period 1894-1908 and the following table gives a *résumé* of the total findings:

	In Good Health	Tuberculous	Died of Tuberculosis	Died of Other Diseases	Total
Idiopathic pleurisy with effusion	228	130	115	41	514
Idiopathic dry pleurisy	23	16	8	10	57
Rheumatic pleurisy	28	3		10	46
Pleurisy accompanying nephritis	6			6	12
Pleurisy accompanying typhoid fever	3			1	4

Koster first considers in detail the 514 cases of idiopathic pleurisy with effusion. Of these 47.7 per cent. became manifestly tuberculous or died of tuberculosis! Still more significant is the incidence of tuberculosis in these cases when the various ages are considered. Children proved to have a fairly good prognosis in reference to this point, while the incidence of the disease rose at about the fifteenth year and remained high until the sixtieth year, over a half of persons with a history of antecedent pleurisy at any of these ages having developed tuberculosis or died of the disease. This conclusion coincided with Allard's findings.

The next point considered by Koster is the interval of time which interposes between a pleurisy with effusion and the development of manifest tuberculosis. As is well known, many writers, and especially Landouzy, claim that every idiopathic pleurisy with effusion is a symptom of existing, though perhaps latent, tuberculosis, and Koster's findings lend much statistical support to this view. He has found, namely, that in those who died of tuberculosis in his series over 85 per cent. died in the course of the first *five* years after the incidence of pleurisy. This finding is likewise in agreement with Allard's.

Koster next considers dry pleurisy and shows that of the persons who had suffered from this affection not less than 42 per cent. later developed manifest tuberculosis or died of it, the disease developing or fatal outcome occurring within the first five years after the pleurisy in two-thirds of the cases. On the other hand, persons who had suffered from a pleurisy with a distinct etiology, that is, of rheumatic nature, or one occurring during nephritis or typhoid fever, only occasionally later developed tuberculosis or died of it.

Koster's conclusions deserve to be given *in extenso*.

1. In persons over fifteen years of age tuberculosis develops in at least one half of the cases after the occurrence of idiopathic pleurisy with effusion.

2. In children under five years this occurs in one-third of the cases only.

3. Statistics show that tuberculosis developing after wet pleurisy in older persons runs an acute course and has a bad prognosis.

4. After idiopathic dry pleurisy, too, about 40 per cent. of the cases develop manifest tuberculosis. This form of pleurisy is rare in children.

5. In the great majority of cases tuberculosis becomes manifest within five years after dry pleurisy or pleurisy with effusion.

6. Tuberculosis develops only exceptionally after pleurisies with definite etiology.

The author expresses surprise at the varying standards of judging the degree of risk in insuring persons with a history of idiopathic pleurisy. He thinks that no such person should be insured at all until five years have elapsed since the occurrence of the disease. After this period the risk is diminished, but is still present, diminishing with each additional year. On the other hand, history of a pleurisy with a definite etiology should not debar an applicant from insurance, if he is otherwise acceptable. [Koster's paper contains many other valuable data and tables which cannot be summarized here and for which the medical director or examiner would do well to consult the original article.]—*Zeitschrift für klinische Medizin*, Volume 73, Nos. 5 and 6.

Syphilis and Life Insurance.—Mild, well-treated cases should be charged 10 per cent. extra until the expiration of six years. When tertiary symptoms have developed the proposal should be absolutely declined, because, while treatment may temporarily remove these, it cannot eradicate the tendency to recurrence. These cases rarely live beyond ten years, and often much less, as treatment is usually insufficiently continued. Greene advises that "under no circumstances should a straight life-policy be issued to anyone who has a syphilitic history. The Actuarial Society of America has shown that an excessive mortality is experienced, despite careful selection—a much heavier death rate than in the case of past hip-joint disease." Actuaries find that in those in comfortable circumstances who have been insured most deaths from syphilis occur after the age of fifty. Actuaries dislike to grant insurance to applicants beyond this age, except at a high premium, but sanction endowment policies payable at the age of fifty.—"Syphilis, Its Diagnosis, Prognosis, Prevention and Treatment," by Thomas Hugh Beddoes, 1910.

Clinical Interpretation of Urinary Analysis.—Marcel Labbe agrees with M. Leven that there is much danger in having patients compare the urinary findings furnished for them by analytical chemists with the "normal" findings usually printed on the same sheet. Such persons frequently imagine themselves ill of various diseases because of discrepancy between their urine and the normal values; occasionally they treat themselves for various symptoms which they refer to the kidneys. Labbe thinks that such "normal" findings are misleading even for the physician, for they tempt him to forget that to interpret urinary findings one must take into consideration the food of the patient, his physical condition, his age, etc. etc. Many physicians, for instance, prescribe various phosphates or phosphoric acid preparations, because a single examination of the urine shows a deficiency in these elements. Frequently an excess of nitrogen and occasional glycosuria is interpreted as meaning a disease of the pancreas. Uric acid determinations, if they give high values, are interpreted as signs of gout or other forms of arthritis. It is, therefore, best to take none of the urinary findings as standard for comparison, but to compare the results of analysis with the theoretical values which may be considered normal only for the individual under examination.—*Journal de Médecine de Paris*, December 2, 1911.

Book Reviews.

A Text-Book of the Practice of Medicine. By James M. Anders, M.D., Ph.D., LL.D.; Professor of Medicine and Clinical Medicine at the Medico-Chirurgical College; Physician to the Medico-Chirurgical Hospital, Consulting Physician to the Jewish Hospital and to the Widener Home for Crippled Children; formerly Physician to the Philadelphia and to the Protestant Episcopal Hospitals, Philadelphia; Officier de l'Instruction Publique. Illustrated. Tenth edition, thoroughly revised. Price $5.50. Philadelphia and London: W. B. Saunders Company, 1911.

This work has apparently earned a wide popularity, as evidenced by the fact that it has already passed through nine editions. It follows the traditional lines laid down for the one-volume textbook on practice, but particular emphasis is laid on etiology, diagnosis, and treatment. The matter has been brought right up to date in the inclusion of the following new topics in this edition: the abortive type of plague, masked chlorosis, polycythemia hypertonica (erythrocytosis), blocked pleurisy, angina major, angina minor, angina abdominis, hour-glass stomach, appendix dyspepsia, fatty liver, heat cramps, serous meningitis, tic, and psychasthenia. New and rewritten matter includes the following: Coleman on milk-sugar in typhoid fever, Chantemesse's serum in typhoid fever, Brudzinski's signs in cerebrospinal meningitis, tonsillectomy in acute articular rheumatism, Falk's and Tedesko's test in chronic tuberculosis, artificial pneumothorax in pulmonary tuberculosis, Nastin treatment of leprosy, appendicostomy in chronic amebic dysentery, Ehrlich's remedy in sleeping sickness, salvarsan in syphilis and in malaria, Bass' method of examining feces in uncinariasis, the Wassermann reaction in syphilis, Grawitz's treatment of pernicious anemia, transfusion of blood in pernicious anemia, autoserotherapy in serofibrinous pleurisy, Holmgren's treatment of serofibrinous pleurisy, Broadbent's sign in aortic regurgitation, Oertel cure in chronic myocarditis, Gordon's method of determining myocardia, Klotz's experiments on arteriosclerosis, salt-free diet in arteriosclerosis, colon bacillus producing ulcer of stomach and duodenum, glycyltryptophan test in cancer of stomach, Goodman's modification of Solomon's test in cancer of stomach, Boas' method of diagnosis in intestinal catarrh, hemohepatogenous jaundice, chronic family jaundice, chronic cholecystitis, autoserotherapy in ascites, Boston's test for albuminuria, Martinet's method of estimating acidity of urine as a basis for treatment, Schapira's test for permeability of kidney, McBride's treatment of alcoholism, neuritis, neuralgia, anterior poliomyelitis, tumors of spinal cord, aphasia, cerebral palsies of children, Breuer's and Freud's theories of hysteria, and the analytical method of treating hysteria. The work is well written, and exceptionally free from error, and may be recommended to the student and general practitioner as a modern textbook on the practice of medicine.

Operative Obstetrics, Including the Surgery of the Newborn. By Edward P. Davis, M.D., Professor of Obstetrics, Jefferson Medical College, Philadelphia. With 264 Illustrations. Price $5.50 net. Philadelphia and London: W. B. Saunders Company, 1911.

This excellent volume is the most complete presentation of the subject of operative obstetrics which has thus far appeared in this country. A book of this kind is very timely and Dr. Davis is to be congratulated upon the complete and yet very concise manner in which he has succeeded in presenting this subject. The book is divided into four parts, the first of which deals with the surgery of pregnancy, the second with that of labor, the third with the surgery of the puerperal period, and the fourth with that of the newborn infant. The author's recommendations as regards operative interference, although generally conservative, are in thorough accord with the accepted teachings of the day, and his own standing as an obstetrical operator gives to his book the stamp of truth and authority. The chapter on forceps, particularly, is well worth the attention not only of the general practitioner, but also of those who desire to practise obstetrics as a specialty, for, notwithstanding the almost universal application of this obstetrical aid, its mechanical opportunities and clinical applications are by no means as well understood as they ought to be. Dr. Davis emphasizes the necessity of careful application and the use of the most appropriate form of instrument in each particular case. There is one recommendation, however, in using the axis traction instrument which might be questioned, and that is the use of the foot (as described on page 166) in applying traction to a loop of tape applied to the forceps. This appears to be a very unsafe recommendation for general application. We are glad to note that the author insists on limiting the use of forceps to a head that is fully engaged and molded and pointing out the danger of the instrument in those cases in which the head is not engaged or just beginning to enter the brim.

The section devoted to the cesarean operation, both vaginal and abdominal, is in accord with the teachings of the day, although one might question the advisability of delivering the uterus in the abdominal type of operation before extracting the child. The author is inclined to favor the Porro operation for infected cases if vaginal delivery is impossible and in twelve patients operated upon by the author, by this means, recovery took place in all. This operation has been more or less discredited in recent years and unjustly so. The writer does not, apparently, favor to any great extent the operations advocated for dividing the pelvic bones, and this stand will probably prove to be in accordance with American practice in the future.

The book is quite satisfactorily illustrated by a selection of reproductions from the works of other authors, very few original illustrations being introduced. In view of the general adoption of rubber gloves during delivery, their absence in many of the illustrations is noteworthy. As a whole Dr. Davis's book is very worthy of praise because, as already stated, it represents the first effort by an American obstetrician to produce an extended work on this subject as such.

Aphorismen für die Hals-, Nasen-, und Ohren Ärztliche Praxis, von Dr. Franz Bruck. Berlin-Charlottenburg: Verlag von August Hirschwald, 1911.

In this monograph of thirty-nine pages are numerous pertinent sayings based upon an apparently extensive clinical experience.

A Practical Handbook of the Diseases of the Ear. For Senior Students and Practitioners. By William Milligan, M.D., Aurist and Laryngologist to the Royal Infirmary, Manchester; Surgeon to the Manchester Ear Hospital; Lecturer upon Diseases of the Ear, the Victoria University of Manchester; President of the Otological Section of the Royal Society of Medicine; and Wyatt Wingrave, M.D., Pathologist (lately Physician) to the Central Throat and Ear Hospital, London, and to the Polyclinic, London. With 293 illustrations and 6 colored plates. Price $5.00. London: Macmillan & Co., Ltd., 1911.

The needs of the student, the general practitioner, and the aurist are all admirably served in the pages of this volume, which represents one of the best manuals on diseases of the ear that have appeared in recent years. Within the compass of 596 pages the authors have succeeded in covering the entire field of this subject, nothing of value being omitted. Considerable emphasis is placed upon the importance of applying pathological data, and the results of clinical pathology, in attaining accurate diagnosis and treatment. There are included a chapter upon those diseases of the nasal cavities which have a special bearing upon diseases of the ear; and one upon disease of the ear in relation to modern medicine. Among the other topics fully discussed are the relation of aural disease to life insurance, simulated deafness, facial paralysis, and the intracranial complications of middle-ear disease. The book is well written and profusely illustrated, while the printing and binding leave nothing to be desired.

Nursing in the Acute Infectious Fevers. By George P. Paul, M.D., Town Health Officer, Round Lake, N. Y.; sometime Visiting Physician to the Samaritan Hospital at Troy, N. Y. Illustrated. Second Edition, Thoroughly Revised. Price $1.00. Philadelphia and London: W. B. Saunders Company, 1911.

This new edition contains chapters on acute anterior poliomyelitis and paratyphoid fever; also additions and revisions in the chapters on reduction of fever, alleviation of symptoms, detection of complications, examination of urine, and poisons and their antidotes. The book is well balanced, and the author has shown much skill in what he has omitted; so that there is very little in it that the nurse will not be able to utilize, and it contains practically all that is necessary.

Verhandlungen des Vereins Deutscher Laryngologen, 1911, herausgegeben in Auftrage vom Schriftfuhrer, Dr. Richard Hoffman. Dresden.

This contains the business sessions and records of the present year, followed by thirty-one excellent clinical papers.

Conduct and Its Disorders Biologically Considered. By Charles Arthur Mercier, M.D., F.R.C.P., F.R.C.S., Physician for Mental Diseases to Charing Cross Hospital; Examiner in Mental Diseases and Psychology in the University of London; Visitor of the State Inebriate Reformatory, etc., Author of "Psychology, Normal and Morbid", "A Textbook of Insanity," "Sanity and Insanity," "Criminal Responsibility," etc. Price $3.45. London: Macmillan and Co., Limited, 1911.

It is pointed out by the author that although many works have been written on different departments of conduct there has been none that takes up the study of conduct as a whole. This he has attempted to do in the present volume. Human conduct is investigated from the biological viewpoint: the positive or negative value of every kind of conduct is appraised in proportion as it tends to further or diminish the chances in the struggle for existence. The first book is devoted to the various phases of action: action as spontaneous or elicited; abundant or scanty; instinctive or reasoned; self indulgent or self-restrained; impulsive or deliberate; voluntary or involuntary; novel, habitual, or automatic; original or imitative; crude or elaborate; work or play; and skilful or unskilful. There is also a chapter on instinct and reason, the fossilization of reason into instinct, and the liquidation of instinct into reason. The second book deals with the purposes or ends of conduct and the means by which these ends are compassed. Among the many aspects of conduct that are described may be mentioned social conduct; the social instinct; social inhibition; self consciousness; ambition, pride, vanity, conceit; elicited morality; custom and fashion; patriotic and philanthropic conduct, chastity and modesty; courtship; jealous conduct; marital conduct; parental and filial conduct; recreative and esthetic conduct; investigation, and religious conduct. This enumeration gives but an incomplete and vague outline of the comprehensive scope of this work, dealing as it does with a subject that vitally concerns not only the alienist, but also the general practitioner, whose daily work brings him close to the heart of humanity, and who as the family adviser is frequently called upon for light and guidance. The successful physician is, consciously or unconsciously, a psychologist. The author's mastery of the science of mind and his knowledge of human nature, both normal and pathological, are stamped on every page. His style exhibits a wonderful precision in the choice of words, a quality demanded by the delicate shades of meaning that are associated with this subject. To illustrate: in discussing filial conduct the author notes that "as age advances, the respective parts of parent and child are first modified, and at length reversed. Command on the part of the parent is softened into exhortation; and exhortation is modified into advice. Prohibition is replaced by warning, and warning by friendly caution." As an example of elegance of diction may be cited the following passage in which the author describes the rôle of sexual modesty in the male, in whom, although excessive modesty rarely or never leads to suppression of the sexual instinct, nevertheless frequently embarrasses him in the pursuit of courtship. "Love impels him to court the woman of his choice, modesty inhibits him from open admiration. Even when time, place, and circumstance are favorable, even when he has gained a private interview, and longs to declare his passion, modesty intervenes, and imposes an unconquerable obstacle. He is bold enough, and glib enough, when the object of his affections is not by; but in her presence modesty ties his tongue, confuses his mind, and makes his knees to shake; and, without very positive encouragement, he may go away without effecting his purpose." The author employs the touchstone of racial advantage in explaining almost every phase of conduct. Morality has a utilitarian value: it is "that conduct which is found by experience to be socially or racially advantageous." This is not the usual doctrine of morality which is built on the inherent nature of right and wrong. The various manifestations of abnormal conduct are contrasted with those of normal conduct. Thus, in the sane, suicide is most frequently prompted by the loss of what is, at the time, the chief aim of life; in the insane, suicide is prompted by the conviction of unworthiness, sin, and self-abasement. These examples will suffice to indicate the character of this work, which will undoubtedly become a classic in psychological literature.

Die Peroral Intubation. Ein Leitfaden zur Entlernung und Ausführung der Methode mit reicher Casuistik, von Dr. Franz Kuhn in Cassel. Mit 22 Abbildungen. Berlin: Verlag von S. Karger, 1911.

This volume describes the peroral method of giving anesthesia by means of tubes passed directly to the larynx in cases involving nasopharyngeal tumors, sinus, and tongue operations, palatal operations, extensive injuries of the face, and similar conditions. It describes the proper tube to be selected, its proper introduction, the anesthetic to be used, the position of the patient, in short, gives full particulars of the method.

Diseases of Infants and Children. By Henry Dwight Chapin, A.M., M.D., Professor of Diseases of Children, New York Post-Graduate Medical School and Hospital; Supervising Physician of the Children's Department, New York Post-Graduate Hospital; Attending Physician at the Willard Parker and Riverside Hospitals; Consulting Physician to the Randall's Island Hospital; to St. Agnes' Hospital, White Plains, to the Convalescent Home for Children, Sea Cliff, and to the Hackensack Hospital; President of the American Pediatric Society (1910-1911); and Godfrey Roger Pisek, M.D., Professor of Diseases of Children, University of Vermont; Adjunct Professor of Diseases of Children and Attending Physician to the New York Post-Graduate Medical School and Hospital; Adjunct Attending Physician to the Willard Parker and Riverside Hospitals; Attending Physician to the Darrach Home for Children. Second Edition, Revised, with 181 illustrations and 11 colored plates. Price $4.50. New York: William Wood & Company, 1911.

It is a pleasure to review a work such as this, which does not follow in the beaten path of the usual textbook on pediatrics. It bears the impress of originality and shows that the authors' experience in the teaching of graduate students has revealed to them the needs of the general practitioner. In the two years that have elapsed since the publication of the first edition important contributions have been made to pediatrics, and these are incorporated in the present volume. Among these additions may be mentioned an account of vaccine therapy, including a table of dosage, as applied in the treatment of diseases of children. The newer facts in relation to the serum diagnosis of syphilis and its treatment by means of salvarsan are clearly presented. The authors point out the dangers of this drug when administered to children, and state that their results with salvarsan have not been brilliant. Among the admirable features of this book are its compactness as well as its thoroughness. Its pages are, however, not weighted with descriptions of the rarer conditions, with pathological data, or with controversial details. The science of pediatrics as it can best serve the needs of the practitioner is the goal toward which this work is aimed. The chapters on infant feeding are masterly, presenting as they do the methods of modifying milk with the use of various top milks, which methods are more generally used to-day than any other. The simplicity of these methods, which were originated by Dr. Chapin, have shorn the subject of infant feeding of those mathematical subtleties which have been the bane of the student and the busy practitioner. There is a chapter on special examinations which presents in a nutshell the methods of the laboratory which are most available for the diagnosis of diseases in childhood. In the section devoted to the exanthemata there is a series of full-page colored plates which show with wonderful accuracy to life the cutaneous and mucous membrane manifestations of these diseases. There are a large number of photographic illustrations which admirably supplement the text. Considerable attention is given to the subject of treatment, and the numerous prescriptions are particularly helpful. The authors are to be complimented on the excellent manner in which they have accomplished the task of writing a modern textbook of diseases of children.

A Manual of Pathology. By Guthrie McConnell, M.D., Professor of Pathology and Bacteriology, Medical Department, Temple University; Assistant Pathologist to the Philadelphia City Hospital; formerly Pathologist to the St. Louis Skin and Cancer Hospital, and Bacteriologist to the Missouri State Board of Health. Illustrated. Second Edition, Thoroughly Revised. Price $2.50. Philadelphia and London: W. B. Saunders Company, 1911.

This volume contains, in concise form, the essentials of pathology. It is not meant to take the place of standard textbooks on the subject, but it will serve as a guide to the student who, in a limited time, has to acquire the salient features of the subject. In this new edition the chief changes will be found in the chapter on tumors (where Adami's classification is now included) and in the sections on parasites, malaria, and the thyroid gland. The book is well printed and adequately illustrated, and should serve the purpose for which it was written.

Society Reports.

NEW YORK ACADEMY OF MEDICINE

Stated Meeting, Held December 7, 1911

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR

Election of Officers.—*Vice-President*, Dr. Walter B. James; *Treasurer*, Dr. Reginald H. Sayre; *Trustee*, Dr. Charles L. Dana; *Member of Committee on Admissions*, Dr. Floyd M. Crandall; *Member of Committee on Library*, Dr. H. S. Oppenheimer.

The Library Fund.—The President announced that 13,000 duplicate volumes had been sold and the money received for them, $3,000, had been added to the principal of the library fund.

The scientific session was under the auspices of the Section on Obstetrics and Gynecology.

The Importance of Faults of Development of the Pelvic Organs in the Practice of Gynecology.—Dr. EDWARD REYNOLDS, Professor of Gynecology, Harvard University, compared the surgery of twenty years ago with that of to-day. Twenty years ago surgery was resorted to for the purpose of saving the lives of those otherwise doomed to death or to alleviate unbearable pain. To-day most of surgical operations were undertaken for the purpose of improving the health of the individual, and surgery for the prevention of disease was already in existence. Most of this modern surgery was done upon more or less defective individuals, i. e., most of the lesions for the correction of which operations were undertaken were the result of some local imperfection.

It was a general law that developmental imperfections were seldom single, and that the individual who had one such defect usually had others. Consequently the surgeon should not concentrate his attention solely upon one individual local lesion. Dr. Reynolds said he would exclude from consideration those cases of ptosis which resulted from rapid emaciation and loss of the supporting fat as well as those in which the ptosis was merely a part of a general muscular relaxation. These ptoses were never operative. On the other hand, the surgical ptoses always affected a single organ and were usually the result of some developmental defect in the supports of that organ, but, as had been said, such a developmental defect was usually associated with other maldevelopments. The condition commonly referred to as Lane's kink was usually a developmental defect, i. e., an abnormally movable colon (defective supports) in combination with an abnormally fixed terminal loop of ileum. The ptosis of the transverse colon, known as the U-shaped colon, was one in which the stomach and the middle of the colon proptosed together while the angles of the colon were properly supported. This condition might sometimes be due to the weight of great distension in the upright position, but even then it usually occurred only in individuals with defective general development. There was apt to be the same family resemblance in appendices as in noses. Every surgeon knew families in which many or most of the members had had appendectomies. The unfavorable shape of the appendix was liable to cause distension of the appendix in the majority of instances. Constipation was often dependent upon defective development of the intestine. The sigmoid was frequently bent into a sharp angle by its normal adherence to both sides of a left broad ligament which extended too widely and too far posteriorly across the left half of the pelvic brim. This was due to a failure in retrogression from a condition normal in fetal life. In women abnormal development of the so-called preanal pouch was a common cause of constipation. This malformation showed a distinct tendency to appear throughout certain families. Prolapsed ovaries occurred, and could occur primarily, only in individuals with abnormally long ligaments, an atavism to a condition common to their remote ancestors. He had recently seen severe ovarian pain due to a similar atavism in which one ovary was contained in a distinct pocket on the posterior side of its broad ligament, a condition common in rodents and ferae. Anteflexion of the cervix was an important maldevelopment. This condition was normal in a child up to the age of puberty. Observations had shown that it was less an alteration in the shape than a flexion due to a coincident underdevelopment of the anterior vaginal wall and the structures commonly summarized under the name of utero-vesical ligaments. A contraction in the muscular fibers of the so-called uterine ligaments produced an obstruction in the lumen of the cervix such as that made by bending a thick rubber tube. There was a curiously frequent coexistence of the condition known to orthopedic surgeons as the flat-backed, round-shouldered position with these cases of anteflexion of the cervix. The relation of anteflexion of the cervix to dysmenorrhea was due to the fact that the menstrual congestion increased this flexion. This condition might cause sterility by its interference with the upward passage of the spermatozoa by retained uterine secretions. All these abnormalities, as well as many others that might be cited, occurred in otherwise ill-developed individuals, and the main point of value in a discussion of the subject was that the gynecologist should bear in mind that faulty development was seldom single and the woman should be looked over as a whole and treated as a whole. The neurasthenic was always an underdeveloped person and her underdevelopment should be looked at as a whole.

Enteroptosis.—Dr. JOHN G. CLARK, Professor of Gynecology in the University of Pennsylvania, gave a lantern slide demonstration of different varieties of enteroptoses.

Dr. EDWIN B. CRAGIN said that in listening to Dr. Clark the one point that had impressed him was that in the practical dealing with this subject they should be sure they were dealing with a surgical case before they operated. The one point that they should carry away with them was that cases of ptosis due to lack of fat in the tissues were not operative cases. In fact, any case that could be relieved by medical measures was not a surgical case, but any case that could not be relieved by medical measures and presented obstructive symptoms was a case for the surgeon. For many years he had considered anteflexion of the uterus as a fault in development and had taught that the way to treat such patients was to treat the cause of the mal-development or non-development of the uterus and also the result. He could not agree with the statement made by Dr. Reynolds that many of these anteflected cervices would go back into normal shape under the use of an anesthetic. Some would, but in his experience, not many. Mere dilatation followed by the introduction of a sterilized stem would in many instances straighten out the uterus, improve the drainage from it, improve its circulation, relieve the dysmenorrhea, and, at the same time, favor the development of pregnancy. The pregnancy would complete the development of the uterus.

Dr. Cragin said he could not well leave the subject without speaking of the relation of malformations to obstetrics, and the importance of a correct diagnosis in the different forms of duplication of the uterus and vagina. In the uterus bicornis the obstetrician occasionally found the child in one horn and the placenta in the other. He had seen two such cases in the Sloane Maternity Hospital within the last few years. Again

one occasionally found the unimpregnated half of a double uterus obstructing delivery from the pregnant half, or even causing a rupture between the two halves as seen by him not long ago. He had met with a case of double vagina, in which, during a breech delivery, one foot and a loop of cord had come down into one vagina and the other foot in the other vagina. A living child was obtained in this case by rapid division of the septum. These were a few obstetrical complications resulting from faults in development of the pelvic organs.

Dr. Herman J. Boldt said that frequently there were no symptoms at all accompanying anteflexion of the cervix. There was a class of patients, however, that required treatment in the way outlined or otherwise. The results of the treatment were often a matter of the personal equation. Many of these cases of malformation should be treated in a surgical way. Dr. Boldt had seen Dr. Clark operate on one of the cases belonging to the class he had described as requiring operation, and he had been impressed with the fact that he was very careful in the selection of his cases before resorting to surgical intervention.

Dr. Robert L. Dickinson commended the breadth of view of the two surgeons, and wished also to warn against surgery until a full history and a complete study of the individual had been made. The beginning of the examination should include stripping the patient at least to the underclothes, as there were often striking anomalies found in cases of enteroptosis or flexions. As examples Dr. Dickinson had a number of pictures thrown on the screen showing grave defects of development, some general, as in the infantile type; some of the trunk only, as an arrest of development from clothing and indoor life. Acquired defects of attitude were depicted, and also methods of office observation and record. He spoke of the use of temporary support pending general upbuilding and correction. Surgery had a limited but important field as an adjunct to these.

Dr. W. Gill Wylie referred to an article he had written on "The Influence of Imperfect Development of the Generative Organs as a Cause of Disease," which was published in the Transactions of the American Gynecological Society, September, 1891, in which he spoke of the natural tendency to attribute disease to some immediate exciting cause and to entirely overlook the more remote but often real cause, and as a result methods of treatment were based on false ideas and were often useless. For instance, catarrhal endometritis resulting from dysmenorrhea, sterility, etc., was until recently almost invariably attributed to falls causing anteflexion or to exposure to cold during menstruation. This view naturally led to the use of pessaries and other vain attempts to straighten the uterus, to rest in bed during menstruation, to excessive housing of young girls and to excessive limitation of the amount of exercise. The important point that imperfect development of the uterus made that organ an easy prey to catarrhal disease was rarely considered. Many years ago he had recognized the great importance of imperfect development in causing uterine disease. Many girls, from sickness, bad hygienic conditions, or other circumstances, used up the forces that should have gone to develop the genitals and reached maturity with imperfectly developed organs. Among these few escaped having subacute catarrhal disease of the throat, and many of them had similar disease of the mucous membrane lining the cervix uteri. Many of these reached a stage in which pregnancy would not take place; however, later, the general health might improve sufficiently to permit of impregnation, but not before serious structural changes had taken place in the cervix. In cases in which disease was present just after a free menstrual flow the secretions might for a time be nearly normal and impregnation would take place and the mucous membrane of the cervix remain diseased throughout pregnancy. Such cervices were very sure to tear during labor, and even where the laceration was comparatively slight it might be very troublesome. Dr. Wylie recalled several papers he had written in which he had expressed his views in regard to the relation of imperfect development to different pathological conditions of the uterus. When he first published these views little had been written on the subject, but he was convinced that when the profession appreciated the importance of this subject it would greatly influence their methods of preventing and treating the diseases of women. A girl to be sure of full development should have a surplus of physical and nerve force during the period of development; if this force was closely used up by special mental and emotional work or strain, the generative organs would fail to develop sufficiently to perform their functions normally. If a girl was pushed at school, and her force used up by constant contact with older intellectual people, she was almost certain to have a leucorrheal discharge, irregular and painful menstruation, etc., and when examined locally would be found to have an infantile, anteflexed uterus with such disease of the glands and follicles about the cervix as to cause a semi-raw state which they called granular erosions, and the older men treated as ulceration.

Dr. Robert T. Morris said that he was glad to note that in considering defective organs they were taking more cognizance of defective people. Most people showed some stigmata of decadence; but in cases where there was such a distinct feature as the infantile type of uterus they must assume that other stigmata of decadence were present. There were usually a number of developmental defects associated with any one that was most in evidence. He was skeptical with regard to what had been said about auto-infection from a flexed uterus, because he had made cultures often from the interior of such uteri and had so frequently found the contents sterile. Patients with relaxed perineal supports, aside from those in which the condition was due to loss of fat, were usually neurasthenics. Relaxation of the perineal supports was only an incident in a long history. Secondary symptoms, including toxemia, followed in many of these cases and required treatment; but the most important thing was to take into account the fundamental fact of the presence of stigmata of decadence. He had been one of the first to take up the surgery of ptosis and had shortened various ligaments. These patients were apt to make a prompt response, apparently having been benefited, yet within a year they were back with a new group of symptoms. At present he would not resort to surgery in these cases until all the resources of a competent internist had been employed, including abdominal supporters, massage, posture, hydrotherapy perhaps. He would, in fact, make every endeavor to avoid surgery. It was a different matter when they had ptosis of a single viscus, like the kidney, in which secondary symptoms would be relieved, if they made a proper selection of cases.

Dr. A. Jacobi said there was a time when he examined a great many sterile anteflexed uteri, and many of them were the result of insufficient development. Many were cured by operation, but there were a number of instances in which the stimulation of the uterus was effected by the introduction of a sound, with or without the use of electricity, which gradually improved, and in

which pregnancy not infrequently ensued. With regard to the colon, the general practitioner should be warned that the sigmoid flexure was in almost every case adherent; that the sigmoid was long and the ascending portion of the colon short; that the transverse colon began lower than was normal. The sigmoid was so long that it often reached to the median line. This was why a surgeon in Paris insisted in operating on the rectum from the right side and not from the left. Dr. Jacobi had performed this operation many times. Forty-five years ago he had operated upon a baby in which a movement of the bowels could not be secured after vain efforts for five days. The child died of peritonitis, and at autopsy no obstruction was found, only some hardened meconium. The child was not the subject of any mechanical obstruction. Soon after he saw another case in which there were hardened lumps of meconium, but surgery was not resorted to and the child recovered.

Dr. Edward Reynolds of Boston, in closing the discussion, said that the subject of enteroptosis was almost invariably an ill-developed person. It ought to be the universal rule that before any surgeon operated for ptosis he should look over carefully all the viscera and with the patient stripped. He ventured the opinion that if the whole body was looked over nine out of ten surgeons would send these patients to an orthopedic surgeon for instruction in certain forms of gymnastics.

SOUTHERN MEDICAL ASSOCIATION.

Fifth Annual Meeting, Held at Hattiesburg, Miss., November 14, 15, and 16, 1911.

The President, Dr. Isadore Dyer of New Orleans, La., in the Chair.

(*Concluded from page 1209.*)

Pellagra.—Dr. J. S. Turbeville of Century, Florida, discussed the symptom-complex called pellagra. He defined the disease, gave its history and geographic distribution, and discussed its prevalence in the United States.

Etiology of Pellagra.—Dr. John J. Jelks of Memphis drew the following conclusions: Pellagra was not a new disease, nor a disease in fact, but a series of symptoms-complex, the result of parasitic infection in the gut, with consequent abrasions, inroads, as it were, and either absorption of or the conveyance of toxin-developing bacteria or the toxins themselves into the blood or the central nervous system, the force of which seems mostly spent upon the cervical and dorsal portions of the cord. The amebæ seemed capable of conveying these toxins or toxin-developing bacteria, and probably were the chief immediate hosts. Some form of amebæ had been found in the author's cases, and usually many of these organisms had lost much of the hyaloplasm, were immotile, or almost so, and contained many dark particles, a condition not so frequently found as in pellagrins, therefore believed to be significant. He had never observed the degree of prevalence of this morphological alteration in other cases, as in those of advanced pellagra with skin and nervous symptoms.

Pellagra in Tennessee.—Dr. J. A. Albright of Nashville read a paper on this subject in which he presented the conclusions of a commission appointed by the State Board of Health to investigate the number of cases of the disease throughout the State. This commission was composed of Drs. William Krauss, chairman; Byrd L. Rhea and J. C. Brookes. Their conclusions were: (1) The data gathered in the field showed that first cases, as a rule, sprang up in the most remote places. While some of these had been imported from other States, quite as many gave no history of exposure to any person or place infected with pellagra. (2) The disease had appeared rather simultaneously at widely different points, not in any way related to each other, either as to avenue of infection, or as to similarity of local conditions. (3) The epidemic of pellagra in the United States had appeared in disregard of all laws of epidemiology. There had been no route of travel or sequence of development characteristic of infectious diseases. (4) While first cases might appear in disregard of any system of regularity, a large number of cases had apparently become foci for the development of secondary cases. (5) Such secondary appearance failed to sustain either view of the etiology of the disease to the exclusion of the other. Such persons might partake of the infected or poisonous food, contract the disease through the bite of an insect, or might become contaminated in some other way. (6) In some counties there was as yet no evidence of secondary cases, for in one instance the first case appeared seven years ago, and this patient was now living on the bank of a stream. (7) Approximately 97 per cent. of cases admitted the use of corn meal in some form, and, while many were tempted to mislead, there seemed to be authentic cases of abstention from corn in all its forms. No case was reported of the complete absence of corn meal from the premises for a term of years. (8) The prodromal stage, or period of incubation, seemed to vary greatly, but was apparently quite long. The development of the disease appeared in all cases to be gradual. While diagnostic symptoms might appear spontaneously, they must follow a progressive disease of the spinal cord. (9) A large proportion of cases appeared in the wake of or in the course of some other disease. (10) While this was a disease of poverty and bad hygiene, many cases had appeared in the well-to-do families with good hygienic surroundings. (11) Arsenic, especially the arylarsonates, appeared to have a specific curative effect when begun early and persisted in. (12) Failure to seek medical relief, and especially the persistence in bad hygiene and food usually resulted in death or insanity sooner or later. (13) The amelioration or disappearance of symptoms in cold weather suggested a strong influence upon the course of the disease. (14) Pellagra appeared to be a gradually developing, cumulative intoxication of the central nervous system, of indefinite prodromal stage, of seasonal periodicity, the symptoms of which might appear suddenly during the spring, summer or early autumn. (15) There was no proof of its immediate transmission from person to person, though it might be a house infection. (16) Its phenomena could be explained on grounds other than infectiousness, and they appeared to favor the hypothesis of food transmission. The theory of insect transmission did not fit the early isolated cases so frequently found. (17) It was possible that food cereals, and especially corn meal, served as vehicles of transmission, and that the infection existed in granaries and elevators, and that the obstacles to its transmission in this way were great enough to account for the relatively few cases of the disease. (18) Since this possibility had not been definitely disproved it was imperative that there be sanitary supervision of grain distribution. (19) It was imperative that the public be instructed in hygienic living with special reference to house screening, sanitary privies, properly cooked, wholesome food, eaten as soon as prepared, and that medical advice be sought on the appearance of the earliest suspicious symptoms. (20) One needed institutions for the care, treatment and study of pellagrins.

Prognosis of Pellagra.—Dr. C. C. Bass of New Orleans said that of all the cases of pellagra he saw in New Orleans in 1909, over fifty per cent. died during the year. Of 96 cases seen this year, 1911, only four had died, and with the coming of cold weather none of those now under observation would be expected to die. This changed condition, though due partially to the milder type of disease

prevailing in the section around New Orleans, was due chiefly to the fact that mild cases were now recognized; whereas formerly only the severe and frequently hopeless cases were recognized. How long must a patient be free from attacks before he was safe from a return? His observation would lead him to answer that if an attack could be avoided for twelve months or longer, there was little danger of a return of the disease, provided all corn food had been avoided during the time, and that it was never resumed. Another guide to the prognosis in a given case was the condition of the reflexes. Whenever the knee jerks were exaggerated, as they were in all moderate and early cases, indicating irritation of nerve tissue, it was always possible for the patient to recover. In Italy and Roumania, where pellagra had been recognized for a long time, and the medical profession was therefore familiar with it, the mortality was considerably less than ten per cent for all cases. The type of pellagra seen in New Orleans, and coming chiefly from Louisiana and Mississippi, had a mortality not exceeding five per cent for all cases.

Skin Manifestations of Pellagra, with Reference to Their Importance from a Diagnostic Standpoint.—Dr. H. E. Ménage of New Orleans stated (1) that the skin eruption of pellagra was not always a late or terminal manifestation, but might be a very early one. (2) One should be willing to have a diagnosis made of pellagra on the skin lesions and in the absence of the symptom-complex, because if an early diagnosis was made, therapeutic measures might be instituted and thereby save the patient the burden of proving his own diagnosis, which he surely would do if left untreated. (3) The aberrant forms of skin lesions might be and were often due to accidental and incidental causes and not inherent in the initial erythema itself.

Treatment of Pellagra.—Dr. Louis Leroy of Memphis said that in the early stages he had found more uniform benefit from the administration of soamin hypodermatically, starting with one-grain doses every other day, and increasing up to three or more grains to the dose until from seventy-five to a hundred grains had been given, when a period of rest for two weeks was given, followed by another course of the drug, if necessary. He had used atoxyl in the same manner, but he had not had a chance to compare the two drugs critically. He had also used sodium cacodylate, but soamin was preferable. His observation of salvarsan in pellagra was such as to discourage its use, but he admitted that he had not had the chance to administer it according to the method recently recommended by Martin, who reported some good results in giving fractional doses of the drug, repeated at intervals of from a day or so intravenously. For internal administration, he believed he had had more satisfactory results from Donovan's solution than from Fowler's solution, although both had, at times, been very satisfactory.

Dr. Charles W. Stiles of Washington, D. C., knew of no less than ten or twelve species of amebæ reported as parasitic in the human being. When a report was made that amebiasis was very prevalent in a given district, it did not mean anything unless there accompanied that report a definite statement as to which particular kind of ameba was present. It was not strange that investigators of pellagra had recently associated amebiasis with pellagra. It so happened that he had recently examined a large number of Southerners for infection with amebæ and he found that the statistics of infection had not been exaggerated. But an important point to remember was this: the common amebiasis which we had in the Southern States was of the nonpathogenic form. He was not able to agree with Dr. Jelks that the mass of amebic infections in the South had any particular significance to pellagra.

Dr. J. T. Searcy of Tuscaloosa, Alabama, said the cause of pellagra was still an open question, and its treatment related principally to the symptoms. The peculiarity about pellagra was that the toxins which arose affected the psychic center more than any other disease. Patients got psychic symptoms in pellagra more than they did from malaria, from hook worm disease, from typhoid fever, or from any other systemic disease; consequently pellagrins drifted into the insane hospitals.

Dr. H. E. Ménage of New Orleans said that quinine as a therapeutic agent in the treatment of pellagra had not been mentioned. We were indebted to Dr. Isadore Dyer for the suggestion to use quinine in treating cases of pellagra. Cases had been treated with this drug with gratifying results.

Dr. J. A. Hayne of Columbia, S. C., said they had 2,100 cases of pellagra under observation and treatment in that State. Of this number a large proportion were females. So far as the corn theory was concerned, they had gone so far as to forbid the exportation of corn that showed over thirty per cent. total acidity, and they did not allow that corn to be used. He had seen one case of pellagra in a nursing infant, and whether the toxins were carried through the mother's milk or not, he did not know. The infant did not eat corn meal or corn bread. He had seen patients with pellagra who had had nothing to do with corn in any form.

Dr. Charles R. Craig of Washington, D. C., stated that as far back as 1905 he published researches on the examination of the stools of over one thousand men in the city hospital of San Francisco, and fifty per cent. of them showed *Ameba coli*. These men were from all parts of the United States. Merely finding amebæ in the stools did not mean anything. We ought to find out what species we were dealing with, and whether they were of the pathogenic or nonpathogenic variety. With reference to the occurrence of pellagra in connection with amebic dysentery, at the Presidio they had over 2,000 soldiers who had come back from the Philippines, and of the number of cases of amebic dysentery admitted to the hospital, there was no evidence in any of these cases of skin lesions being particularly common in amebic dysentery. He autopsied over three hundred cases, but none of them had pellagra.

Dr. William Krauss of Memphis said in regard to nursing infants and pellagra, that in his experience in the field he saw one case in an infant. He had seen a nursing infant twelve months of age which had contracted the disease at six months, and was getting its nourishment from a healthy mother. In another case the mother had pellagra and was nursing her baby at the time he saw her. At his request nursing at the breast was discontinued, and although the mother had for five weeks suffered from a virulent form of pellagra, and during four of these five weeks she nursed her infant, the infant was in perfect health, so that with respect to the transmission of any poison or toxin through the mother's milk, we had no proof here in either case.

Dr. J. G. Donald of Hattiesburg, Miss., asked whether the profession had reached a point in knowledge of the symptomatology of this disease that they could diagnosis it before the development of the skin lesions. Early diagnosis had been insisted upon, but how early could the practitioner make the diagnosis by the condition of the alimentary organs and the nervous symptoms which accompanied the disease?

Dr. H. M. Folkes of Biloxi, Miss., had seen and treated fifteen cases of pellagra, and of this number four had died. As to the etiology, the preponderance of evidence pointed to the corn theory. The other eleven patients he had treated recovered. Pellagra was not necessarily as fatal a disease as one had been led to believe.

Dr. Louis Kohlheim of Saltillo, Miss., stated that he

had had experience with eleven cases of pellagra. The disease was characterized by the manifestation of nervous symptoms, gastrointestinal disturbances, and skin lesions, and from his limited observation any one of these manifestations might be the first to appear.

Brain Surgery.—Dr. JERE L. CROOK of Jackson, Tenn., reported four cases of brain injury on which he had operated, with gratifying results.

General Treatment of Syphilis.—Drs. A. F. TOOLE and WALTER F. SCOTT of Birmingham advocated an intense, cooperative plan of employing the strongest resolvents and antisyphilitic drugs, the iodides when needful, to afford full play for the other two, mercury by intramuscular injection for a short but reasonable time, and salvarsan intravenously in repeated doses until the serum reaction indicated a cure of the disease.

Eye Lesions and Salvarsan.—Dr. J. COLEMAN O'GWYNN of Mobile said that only the severer grades of optic diseases might be considered as contraindications to the administration of salvarsan. The marked tendency towards relapses demanded the combining of mercurial and iodide therapy with salvarsan in the treatment of ocular syphilis. The routine examination of the eyes of patients before salvarsan administration was desirable to furnish further data as to the effect of salvarsan on ocular conditions.

Salvarsan in the Treatment of Syphilis.—Drs. EDGAR G. BALLENGER and OMAR F. ELDER of Atlanta, Ga., stated that in their experience no symptoms had occurred that prevented patients from taking the full amount of salvarsan indicated, nor had the after-effects of the treatment at any time seemed serious. An effort had always been made to regulate the dose to suit the physical condition and weight of the patient. The freedom from trouble so far experienced was probably due to careful physical examinations of all patients, and a regulation of the dose to suit the condition and weight of each individual. They had also insisted that all patients drink freely of plain water and lithia water the day of the treatment and for two weeks afterwards, in order to dilute well the salvarsan as it was eliminated, and thus prevent irritation of the kidneys. They had given salvarsan 415 times.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. J. M. Jackson, Miami, Fla.; *First Vice-President*, Dr. Frank A. Jones, Memphis, Tenn.; *Second Vice-President*, Dr. D. J. Williams, Ellisville, Miss.; *Secretary-Treasurer*, Dr. Seale Harris, Mobile, Ala., reelected.

Jacksonville, Fla., was selected as the place for holding the meeting in 1912.

College of Physicians of Philadelphia

At a stated meeting held December 6, the subject of "Melena Neonatorum" was discussed, particularly its etiology and treatment by blood-serum injections. The discussion was opened by Dr. Wm. R. NICHOLSON, who expressed a preference for the name hemorrhagic disease or diathesis. A bloody discharge from the bloody bowel is not a necessary symptom. There may be spontaneous extravasation of blood from or beneath and of the mucous membranes or into the subcutaneous tissues, or incoercible hemorrhage may take place from a slight wound such as the divided umbilical cord. The symptoms may appear at birth or a short while afterward, and they usually proceed to a fatal termination. There may be no external hemorrhage and the extravasation of blood may be found only on post-mortem examination. In Dr. Nicholson's opinion the condition is due to some infective process, at times obvious, at other times obscure. Perhaps putrefactive states of the intestinal tract may be a causative factor. Of perhaps a dozen cases that had come under Dr. Nicholson's observation all had proved fatal except one, and in this hypodermic injections of human blood-serum had been made, although the little patient had appeared moribund at the time of the first injection. The result was little short of miraculous. Dr. JOHN EDGAR WELCH of New York City by invitation continued the discussion. In his opinion the disorder under consideration is due to a degenerative change in the epithelial lining of the blood vessels brought about by toxic influences probably originating in the intestinal tract. Hypodermic injection of human blood-serum has proved efficacious not only in cases of the hemorrhagic disease, but also in various forms of infection and intoxication. Dr. Welch cited a considerable number of illustrative cases. Dr. WM. H. HOWELL of Baltimore by invitation discussed the agencies concerned in blood-clotting, as well as those responsible for retardation or failure of this process. It has been shown that several factors are essential for the clotting of blood. Among these are the presence of fibrinogen, the presence of calcium in some form, the presence of thrombin or prothrombin and finally the presence of thrombokinase, contained in blood-platelets and in tissue-extracts. The process is interfered with in the absence of any one of these substances. On the other hand, there appears to be a substance, antithrombin, whose presence normally anatagonizes coagulation of the blood, and which must first be neutralized in some way before clotting can take place. Dr. DANIEL M. HOYT presented a communication entitled "The Therapeutic Application of Parahydroxyphenylethylamine (Tyramine)." He pointed out that putrid meat contained a principle capable of causing rise in blood-pressure comparable to that induced by ergot and adrenalin, and he expressed the view that the stimulating property attributed to the dark cod-liver oil formerly prepared might be due to this substance derived from decomposed cod livers. Physiologic investigation showed that this substance—tyramine—has little or no effect when administered by the mouth, but when introduced beneath the skin or directly into a vein it almost immediately causes definite elevation blood-pressure of transitory duration. Similar results also were obtained clinically.

Pathological Society of Philadelphia

At a stated meeting held December 14 Dr. MOSES BEHREND presented "An Enormous Dermoid Cyst without Symptoms, and weighing Thirty Pounds." The patient was a widow, 48 years old, who presented manifestations of neurasthenia, together with enlargement of the abdomen. She declined for a time to submit to physical examination, but finally, when this was permitted, a tumor was found occupying the abdomen from the pubes to the ensiform cartilage. On operation the growth was found to be a dermoid cyst with characteristic contents. Dr. BEHREND presented also "A Dermoid Cyst Twisted on its Pedicle Successfully Removed from a Nullipara Sixty-eight Years Old." The patient had suffered for a numbers of years from attacks of pain in the right iliac region, lasting for varying periods of time and looked upon as due to appendicitis. The final attack was of such severity that operation was resorted to, despite the patient's years. A dermoid cyst was found in the right iliac fossa with signs of localized peritonitis. The appendix was distorted as though it had been involved in the inflammatory process. Dr. GEORGE W. OUTERBRIDGE presented a specimen of "Endothelioma of the Ovary" obtained from a patient whose uterus and appendages were removed on account of multiple fibromata. Both ovaries appeared normal to the naked eye, but on section one of them contained a small new-growth that presented a histologic structure suggestive of endothelioma. There were many connective tissue trabeculæ, some of which were surmounted by a single layer of columnar epithelium. Dr. PENN GASKELL SKILLERN, JR.,

presented "An Anomalous Sigmoid Tortuosity of the Cervical Portion of the Internal Carotid Artery." He pointed out that normally the internal carotid artery exhibits a sigmoid curve close to its entrance into the temporal bone, obviously having the effect of lessening the impact of a large column of blood upon the cranial contents. The specimen shown presented a second curvature of like character at a lower level. Dr. F. E. KEENE exhibited two specimens of "Hydronephrosis due to Aberrant Renal Vessels." In both the condition was recognized by the use of the ureteral catheter and the injection of a solution of a silver salt, followed by the taking of an *x* ray picture. In one instance the condition was situated on the left side, in the other on the right side. In both an aberrant renal artery was present, and to the constriction of the ureter occasioned by this the dilatation of the pelvis of the kidney was attributed. Dr. KARL F. MEYER described the condition of "Contagious Abortion in Cattle; Isolation of the Causative Agent." Dr. WILLIAM G. SPILLER presented a communication entitled "Multiple Hemorrhagic Endothelioma of the Brain," and he exhibited an illustrative specimen. The patient was a man who developed sensory aphasia and later died in convulsions. Autopsy disclosed numerous hemorrhagic lesions in various parts of the brain, and these, upon histologic examination, were found to present the structure of endothelioma. Dr. Spiller had never seen a similar case, nor did he know of any recorded in the literature. Dr. ERWIN C. SMITH, Pathologist in the Bureau of Plant Industry of the Department of Agriculture, of Washington, D. C., by invitation presented a communication entitled "Crown Gall," with lantern demonstration. He expressed the view, based on observations covering a period of eight years, that the formations under consideration presented a number of analogies with malignant disease in men, and he undertook to sustain this view by means of pictures thrown upon the screen.

New Instruments.

AN IMPROVED NEBULIZER.

BY H. DUDLEY YOUNG, M.D. (HARV.)

PORTLAND, ORE.

THE inhalation or vapor treatment plays such an increasingly important part in our methods of treating affections of the respiratory tract that a brief description of a modified nebulizer will, I trust, not be unwelcome. During the past sixteen years I have used and familiarized myself, more or less, with the various nebulizers in general use and in looking over the whole array, there is apparently considerable room for improvement. For the past two years I have made a minute study of this apparatus, not only from the standpoint of the requirements of the specialist, but with a view that it might also prove of value to the general practitioner, as I believe its sphere of usefulness should be broader. Aside from this, I have endeavored to provide an arrangement of simplicity, convenience, and compactness, not forgetting to make it ornamental as well as useful.

Fig. 1 shows the nebulizer mounted on a beautifully finished cabinet made of Oregon fir. The cabinet measures 28 inches deep, the height and length being 30 inches respectively. It contains 8 instrument drawers, enameled inside, a slide, closet and a plate glass top around which are nickeled trimmings. The pressure tank is concealed within the back part of the cabinet. On the left of the cabinet may be seen the copper tube which connects to a pump or any other means of obtaining pressure.

The nebulizer, as seen mounted above the cabinet, has six glass flasks for medicaments and one large storage or receiving flask where the vapor from one, two, or all flasks mixes automatically, this being accomplished simply by opening the valve or valves of any one or more of the flasks desired. The pressure gauge A registers the amount of pressure in the tank. B is another pressure gauge, more delicate than the other, graduated by half pounds. This is placed directly over and communicates with the mixing flask and registers the exact pressure that the patient is receiving. I think that the present is the first nebulizer to register accurately the pressure that the patient receives. On all other apparatus, the gauge plays the part of a "middleman" and registers the pressure in the channel between the valve *from* the pressure tank and

Fig. 1.

up to the valves opening into the flasks. I used to believe, without thinking, that my patients were receiving all the way from 10 to 20 or more pounds of vapor pressure when in reality they were getting only a fraction of a pound.

I would call attention, at this point, to the fact that the hard rubber vaporizing tubes all but touch the bottoms of the six flasks and will therefore take up the last drop of fluid. E is the vapor outlet and vibrator arrangement. I have made a special study of interrupted currents of vapor in the treatment of Eustachian and middle-ear disease, and most authorities are now agreed as to their great value. I therefore studied a plan whereby these interrupted currents might not only be given slow enough to count them, but that it might be possible to increase

their speed and minuteness so that they would exercise a massaging effect on the mucous membrane of the entire respiratory tract. I feel justified in saying my efforts have met with great success. In fact, am convinced that I have added to the nebulizer a most important piece of mechanism.

The reader is referred to the upper diagram on Fig. 2. As a matter of convenience in explaining, let us term this cut "the vibrator." The flask in the drawing is the mixing flask, the large one shown by letter C on Fig. 1. The shaded ring above it is where the vapor enters this flask from the six smaller flasks. It then passes out through tube 9 straight along as shown by succeeding arrows and into the dispensing tube, as may be clearly seen on Fig. No. 1. Should it be desired to give a steady flow of vapor, all vibrator valves are closed, *i.e.* Nos. 1, 2, 4, and 5. For a direct steady flow of vapor combined with air (as a matter of dilution) open valve 1. For very slow interrupted currents or discharges of a greater degree of pressure for inflating the Eustachian tube, move lever 8. Rapid

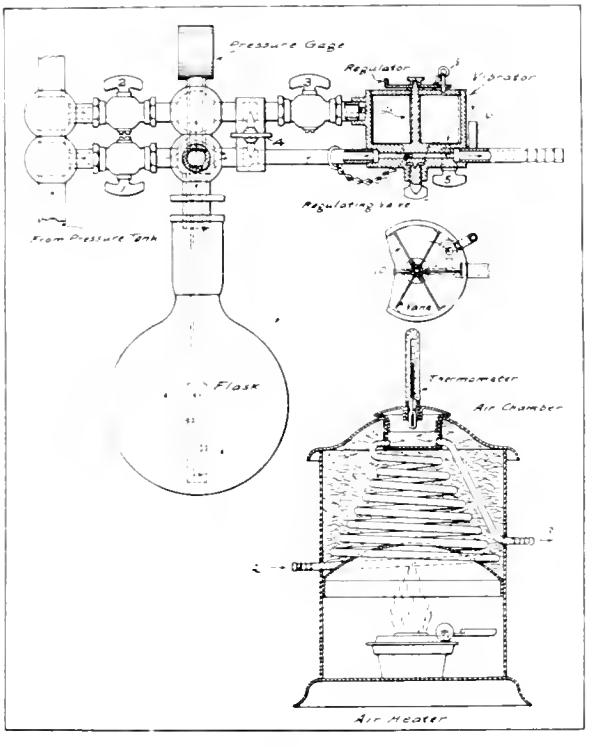

Fig. 2.

interruptions or vibrations even as high as 30,000 per minute are possible with 4 or 5 pounds pressure.

These vibrations may be given in three different ways: (1) For vibrations produced by the vapor itself, open valves 3 and 4. (2) For vibrations operated by air pressure, the air escaping at 6 and only vapor passing to patient, open valves 2 and 3. (3) Vibrations of vapor and air mixed, open valves 2, 3 and 4. Or open valves 1, 3 and 4. Should a measured quantity of vapor or air or both combined be desired for inflating the Eustachian tube and to be liberated at once, this is easily accomplished by simply moving the lever at 8. The vapor may be diluted with pure air by opening valve 1. The thumb screw 7 is used to adjust the vibrator so as to diminish or increase the number of vibrations as the case may require.

The above arrangement does away with the necessity of an aural masseur. Close valve 5 and open valves 2 and 3, the air will escape at 6, place a hard rubber ear nozzle in the dispensing rubber tube and you have a perfect aural masseur. If it is desired to use spray tubes, the automatic cut-off can be attached to the dispensing rubber tube in a second and open valve 1 for pressure.

The vibrator proper, as will be noticed from the diagram (Fig. 2, No. 10), consists of six vanes below which is a valve having two openings at right angles so that each revolution makes four vibrations. This vibrator addition, aside from the important part it plays, makes a very striking appearance on the nebulizer. It looks highly complicated while in reality it is so simple that a child can operate it.

The second diagram on Fig. 2 represents a heater that can easily be attached to any nebulizer. It consists of a series of coils starting from the edge of the dome above the chamber, which is heated by gas or alcohol flame, and continues in a conical shape at the top to a little chamber where the vapor comes in direct contact with the thermometer before the patient receives it. The dispensing tube from the nebulizer is attached at 12 and a tube at 13 is attached to conduct the heated vapor to the patient. The arrangement is so simple that the diagram is self-explanatory. The shading represents asbestos wool packed over the coil to confine the heat. The thermometer will register up to 650°. By means of this little apparatus, which is only ten inches high by five in diameter, the vapor may be given at any desired temperature.

Regarding face masks and hard rubber nozzles, I long ago discarded them as uncleanly. I use individual glass tubes which are carefully washed after each treatment and placed in a small screw-top glass vial containing alcohol. The patient's name is labeled on the vial. When the case is finished the tube and vial are thrown away.

In conclusion I desire to express my thanks to the Harvard Nebulizer Mfg. Co. of Portland, Ore., who have made this apparatus for me in a most satisfactory manner.

Radiotherapy and the Artificial Menopause in the Treatment of Fibromata and Hemorrhages at the Menopause.—P. Oudin and A. Zimmern claim that in radiotherapy we have an efficient method of control for the hemorrhages of the menopause, whether they result from sclerosis, congestion, or fibromata. The rays used after a few applications affect the Graafian follicles and cause atrophy, while leaving the internal secretion intact. A premature menopause natural in type is created, and the mucopurulent discharge and edema of the legs and feet are relieved along with the hemorrhages. In the case of young and small fibromata the size of the growth is reduced from one-third to one-half. In older and larger fibromata and in the subserous type the action is not so good. There is no tendency to obesity caused by the treatment. The effects are not so good in cases under the menopause age as in those of women having fibromata at that period.—*Journal de Médecine de Paris.*

Sporotrichosis Septicemia and Anemia with Febrile Course.—Curcio Antonio describes a form of disease localized in the bones and skin due to sporotrichosis and simulating syphilis or tuberculosis. The disease is due to the growth of the pathogenic fungus sporotrichum, a saprophyte. It causes skin lesions similar to pityriasis and trichopyton. There are three forms: cutaneo-dermic; a form with localized gummata and lymphangitis without ulcerations; and another with lesions that are mucous, muscular, osseous, synovial, etc. Some cases are slow and insidious in their beginning, others rapid and inflammatory. Generally the lesions are indolent, torpid and chronic, accompanied by little pain. In rare cases anemia and cachexia are produced. The prognosis is good except in the mucous or laryngeal forms. The patient seen by the author was a girl who presented a gummatous inflammation affecting bones, muscles, periosteum, articulations, and skin. Treatment with iodides is somewhat unsatisfactory.—*Il Policlinico.*

Medicolegal Notes.

Malpractice — Sufficiency of Evidence — Waiver of Privilege by Suing Physician.—A patient recovered a judgment in the court below against his physician for malpractice, and the physician appealed. It appeared that the plaintiff fell from the steps of his house and struck upon his shoulder, and was treated for the injury by the defendant. The plaintiff's evidence tended to show that his shoulder was dislocated, and that he was not properly treated for a dislocation. The doctor had treated the plaintiff for a considerable time before the injury for a chronic contagious disease, and his theory was that the shoulder was not dislocated, but bruised, and that infection from the contagious disease attacked the shoulder joint following the bruise, and he treated him accordingly and informed him fully as to his condition. The plaintiff did not deny taking the medicine prescribed for the chronic disease, or that the defendant informed him that his trouble was caused by such disease. The appellate court thought the judgment was not fairly sustained by the evidence.

The court below excluded evidence as to the nature of the disease for which the defendant had previously treated the plaintiff as a privileged communication between patient and physician, to which the defendant excepted. It was evident that the defendant could not by experts show to what extent the present condition of the plaintiff might be due to a chronic disease unless he was able to show what the disease was. By bringing an action against his regular physician who had been treating him for a disease, claiming that the subsequent treatment was malpractice, the plaintiff waived the professional privilege, and the defendant was permitted to show any facts he knew bearing upon the present condition of the plaintiff. The ruling excluding the evidence as to the chronic disease was held to be prejudicial to the defendant, calling for a reversal of the judgment.—Terier v. Dare, New York Appellate Division, 131 N. Y. Supp. 51.

Physicians' Defense Company Held an Insurance Company by Federal Court.—The Physicians' Defense Company sought to restrain the insurance commission for the State of California from threatened interference with its business by proceedings to require it to conform to the provisions of the State statutes regulating the business of insurance therein. The sole question presented in the case was whether the business in which the company is engaged is that of insurance, and thus subject to the supervision of the insurance commission. That question depended upon the nature of the contracts issued by the company to its patrons, that is, whether they were contracts of insurance. The purposes for which the company is organized, as stated in its articles of incorporation, are "to aid and protect the medical profession in the practice of medicine and surgery by the defense of physicians and surgeons against civil prosecution for malpractice." Its plan of business was set forth as the issuance to physicians and surgeons, upon stated and agreed compensation, of contracts to defend the holder, at its expense, against any action for malpractice, but not assuming the payment of any judgment for damages for malpractice rendered against the holder.

It was contended by the company that, as indicated by their terms, the contracts issued by it were purely contracts for personal services and embraced none of the essential features of a contract of insurance. It was held, however, that the company was engaged in the business of insurance within the meaning of California Civil Code, Section 2527, providing that insurance is a contract whereby one undertakes to indemnify another against loss, damage or liability arising from an unknown or contingent event, and Section 2531, providing that any contingency or unknown event, whether past or future, which may indemnify a person having an insurable interest or create a liability against him may be insured against.

The company argued that the element of indemnity was wholly eliminated by the provision which exempted it from obligation to pay the judgment; and that all it contracted to do was to secure competent counsel and, at its own expense, see that the suit was properly defended. The court held, however, that the obligation to pay up to a certain amount the costs and expenses, sometimes far exceeding the amount of the judgment, was clearly indemnity; and it was not essential, to make a contract of insurance, that it should indemnify against all loss. It was begging the question to argue that the costs and expense are not the liability of the contract holder, since he does not incur them, but of the company. The obligation rests upon the company, but only by reason of the contract, but for which it would have rested upon the defendant physician.

It was therefore held that the company was subject to the provisions of the statutes of the State regulating the business of insurance therein. In this the court agreed with the holding of the Minnesota supreme court and disagreed with those of the Illinois and Ohio courts, all interpreting the same contract.—Physicians' Defense Co. v. Cooper, 188 Fed. 832.

Penalty for Practising Without a License—Advertising Under Another's Name.—In an action for a penalty for practising without a license it appeared that the State board of health had revoked the defendant's license by virtue of Section 6 of the Illinois Medical Practice Act (Laws 1899, p. 275) for advertising under a name other than his own, and other unprofessional and dishonorable conduct. The defendant contended that the section was void for uncertainty; was repealed by an act of May 11, 1901; is unconstitutional because it confers judicial powers on the State board of health, and violates the State and federal constitutions.

It was held that the section of the act was not void for uncertainty, because it did not catalogue specifically every act of unprofessional or dishonorable conduct which would justify the refusal or revocation of a license. The act of May 11, 1901, is not inconsistent with the section and therefore does not repeal it by implication. The section deals with the licensing of physicians to practice and does not create or define any criminal act. The later act deals with the practice of physicians, and declares that certain acts shall constitute criminal offenses.

Neither the granting nor the revocation of a license to practice medicine is the exercise of "judicial power," as that term is understood in reference to the distribution of the powers of government. It was not contended that the State has not the power to prescribe the qualifications of physicians practising medicine and to punish unqualified persons engaging in such practice, and the existence of such power is not debatable. The possession of the required qualification must be ascertained by some authority, and the legislature has imposed this duty upon the State board of health. To the extent to which the board exercises discretion and judgment in determining whether or not an applicant possesses the required qualifications, its action is no doubt judicial in character, but it is not the action of a court or action appropriate for a court. The State board has power to revoke its own licenses on grounds declared by the statute to constitute a disqualification for the practice of medicine.

The section is not in violation either of the State or the federal constitution. A citizen may advertise his business in any legitimate manner, but it is a legitimate exercise of the police power in protecting the public against the deception and fraud practised by irresponsible pretenders and quack doctors to require every physician to have the license of the State board of health granted in his own name and to practise or advertise under no other.

It was objected that Section 6 of the act making it penal to practice medicine "without a certificate issued by" the State board of health did not apply to the case of one who has had a certificate issued to him. But the court met this objection by saying that one whose certificate has been revoked is without a certificate as much as one to whom no certificate was ever issued.—People v. Apfelbaum, Illinois Supreme Court, 95 N. E. 995.

Liability for Physician's Malpractice—Third Persons.—A person had a foot crushed by a railroad train and was treated by a physician in the employment of the railroad company. He subsequently brought an action against the company to recover damages for malpractice on the part of its physician in failing to treat his injured foot in a proper manner. There was no obligation upon the part of the company to furnish the plaintiff medical treatment. Nor was it under any duty to do so. He was not an employee of the company. The settled rule is, in cases like this, that the person or company employing a physician who by its direction renders gratuitous service is not liable for his specific acts of negligence or malpractice, if reasonable care in his selection was exercised to secure the services of a competent and skillful physician, unless, after his incompetency or unfitness becomes known, or in the exercise of reasonable care should have been known, he is retained. There was no evidence in the case tending to reflect upon the physician's competency or skill except that relating to the plaintiff.

It was held to be immaterial that the plaintiff was not an employee of the company.—Ballard v. Chesapeake & O. Ry. Co., Kentucky Court of Appeals, 130 S. W. 771.

Loss of Diploma in Transmission—Liability Therefor and Masure of Damage.—An applicant for license to practise medicine in the State of Nebraska sent his diploma to the board of health with a request that a license issue to him. The diploma was received by the secretaries of the board, examined, passed upon favorably and, as was their custom, placed in a mailing case, properly directed to the applicant and delivered to the Adams Express Company, one of the leading and responsible express transportation companies in the State, having an office at Lincoln, the point of transmission, and at Superior, the point of delivery. The applicant had given no instructions as to the method of returning the diploma to him, nor had he furnished any postage or other funds to pay for its return. The method of transmission adopted by the secretaries for the return of the diploma to the applicant was the usual and customary method adopted by them for the return of diplomas to applicants for license. The mailing case was received by the applicant at the terminal point named in the direction, indorsed thereon; but the diploma was not therein and was lost. The applicant sued the express company and the secretaries of the State board of health for damages for its loss.

The trial court directed a verdict in favor of the secretaries and the jury returned a verdict for both defendants. On appeal it was held that the selection of the carrier and the delivery of the diploma to it for return was not actionable negligence on the part of the secretaries rendering them personally liable in damages for the loss of the diploma.

The trial court instructed the jury that if they found for the plaintiff against the express company they should find merely nominal damages, and their verdict should be for five cents only. This instruction was criticised by the appeal court on the ground that there was some evidence showing that such a document in the possession of one who had earned it does have an actual intrinsic value. And it was made clearly to appear that it is an inflexible rule of the college (Harvard) never to issue a duplicate under any condition. But as the jury in effect found that the diploma was not lost by the express company the court considered that the instruction was not before it for examination, the question of its value thus becoming immaterial. No sufficient foundation having been laid for a reversal of the judgment, it was affirmed.—Whiteside v. Adams Express Co., Nebraska Supreme Court, 131 N. W. 953.

Qualification to Testify as to Mental Capacity.—In a will contest it was held that witnesses testifying to the mental capacity of the testatrix were not disqualified to give opinions for the reason that they did not hear her say anything about her property or relatives, and therefore could not say that she knew the extent or nature of her property or who were the natural objects of her bounty. Nor were witnesses disqualified to give their opinions as to her mental capacity because they had not first read the will, and did not know the contents. But questions to witness as to whether the testatrix was able to understand the business in which she was engaged when she made the will, or able understandingly to execute it, merely called for conclusions as to her testamentary capacity and were inadmissible as amounting to an attempt to put the witnesses in the place of the jury and allow them to determine the very question which the jury had been sworn to try.—Wetzel vs. Firebaugh, Illinois Supreme Court, 95 N. E. 1085.

Hospital Appropriations.—Kentucky St., § 4711a, appropriated money for the benefit of a certain sanatorium for consumptives. It required the Auditor of Public Accounts to draw warrants for $5,000, being 20 per cent. of the total sum expended in the equipment and establishment of the sanatorium. It gave to other sanatoriums a sum annually equal to 20 per cent. of the amount actually expended in equipment or enlargement, and provided that no sanatorium should receive more than $350 for each bed maintained for patients. In constructing this statute it was held that it evinced a purpose by the State to contribute to the maintenance of institutions for consumptives after their actual establishment. When such an institution enlarges its plant, it is entitled to the increased allowance, but the amount paid a sanatorium must not exceed 20 per cent. of the sum expended in establishing the plant, or in the enlargement thereof, nor exceed $350 a year for each bed maintained for patients, and no bed can be counted which is not in good faith maintained for the patients, though it is not necessary that a bed be occupied by a patient every day in the year.—Association Sanatorium vs. James, Kentucky Court of Appeals, 138 S. W. 377.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

EINFÜHRUNG IN DIE PHYSIOLOGIE, PATHOLOGIE, UND HYGIENE DER MENSCHLICHEN STIMME. By DR. ERNST BARTH. 507 pages; illustrated; paper; price 15 M. Georg Thieme, Leipzig, Publisher.

AN ARMY OFFICER ON LEAVE IN JAPAN. By L. MERVIN MAUS. 413 pages; illustrated; cloth; price $1.50 net. A. C. McClurg & Co., Chicago, Publishers.

LA RÉSPONSABILITÉ ATTENUÉE. By Dr. L. MATHÉ. 128 pages; paper; price 2 fr. Vigot Frères, Paris, Publishers.

THÉRAPEUTIQUE CHIRURGICALE ET CHIRURGIE JOURNALIÈRE. By G. PHOCAS and J. BAROZZI. 1170 pages; illustrated; paper; price 16 fr. Vigot Freres, Paris, Publishers.

TRAITÉ PRATIQUE DES MALADIES DU COEUR ET DE L'AORTE. By ERNEST BARIÉ. 1120 pages; illustrated; paper; price 20 fr. Vigot Frères, Paris, Publishers.

PAIN. By Dr. RUDOLPH SCHMIDT. Translated and edited by KARL M. VOGEL, M.D., and HANS ZINSSER, A.M., M.D. Second Edition. 350 pages; illustrated; cloth; price $3.60. J. B. Lippincott Company, Philadelphia and London, Publishers.

TEXT-BOOK OF MEAT HYGIENE. By RICHARD EDELMANN, Ph.D. 392 pages; with 152 illustrations and 5 colored plates; cloth. Lea & Febiger, Philadelphia and New York, Publishers.

REPORT RELATING TO THE REGISTRATION OF BIRTHS, MARRIAGES, AND DEATHS IN THE PROVINCE OF ONTARIO FOR THE YEAR ENDING DECEMBER 31, 1909. By the Legislative Assembly of Ontario. L. K. Cameron, Toronto, Publisher.

DISEASES OF INFANCY AND CHILDHOOD. Fourth Edition. By LOUIS FISCHER, M.D. 980 pages; with 308 illustrations and 30 full-page half-tone and color plates; cloth; price $6.50 net. F. A. Davis Company, Philadelphia, Pa., Publishers.

CLINICAL DIAGNOSIS. By CHARLES PHILLIPS EMERSON, A.B., M.D. Third Edition. 724 pages; illustrated; cloth; price $5.00. J. B. Lippincott Company, Philadelphia and London, Publishers.

THE FOURTH PHYSICIAN. By MONTGOMERY PICKETT. 144 pages; illustrated; cloth; price $1.00 net. A. C. McClurg & Co., Chicago, Publishers.

THE HEALER. By ROBERT HERRICK. 455 pages; cloth; price $1.35 net. The Macmillan Company, New York, Publishers.

JAHRESBERICHT DER GESELLSCHAFT FÜR NATUR UND HEILKUNDE IN DRESDEN. 168 pages; paper. J. F. Lehmann, München, Publisher.

BERICHT ÜBER SALVARSANBEHANDLUNG AUS DEM KAISERLICHEN MARINELAZARETT KIELWIK. By Dr. GENNERICH. 80 pages; paper; price 2.40 M. August Hirschwald, Berlin, Publisher.

HEART SOUNDS AND MURMURS: THEIR CAUSATION AND RECOGNITION. By E. M. BROCKBANK, M.D., F.R.C.P. 56 pages; illustrated; cloth; price 2/6 net. H. K. Lewis, London, Publisher.

MANUAL OF PHYSIOLOGY. By H. WILLOUGHBY LYLE, M.D., B.S., F.R.C.S. 747 pages; illustrated with one plate and 135 figures in the text; cloth; price $4.00. Oxford Univ. Press, New York, Publishers.

ÉTUDE SUR LES FRACTURES DE L'EXTRÉMITÉ INFÉRIEURE DE L'HUMÉRUS CHEZ L'ENFANT. By Dr. ANDRÉ TREVES. 288 pages; illustrated; paper; price 10 frs. G. Steinheil, Paris, Publisher.

A HANDBOOK OF MEDICAL DIAGNOSIS. By J. C. WILSON, A.M., M.D. Third Edition; 1438 pages, with 418 text illustrations and 14 full-page plates; cloth; price $6.00. J. B. Lippincott Company, Philadelphia and London, Publishers.

A MANUAL OF FEVERS. By CLAUDE BUCHANAN KER, M.D., F.R.C.P. 314 pages; illustrated; price $2.50. Oxford University Press, New York, Publishers.

TUBERCULOUS DISEASES OF BONES AND JOINTS. By Sir W. WATSON CHEYNE, Bart., C.B., F.R.S., F.R.C.S., D.Sc., LL.D. 404 pages; illustrated; cloth; price $5.50. Oxford Univ. Press, New York, Publishers.

THE MECHANICAL FACTORS OF DIGESTION. By WALTER B. CANNON, A.M., M.D. 227 pages; cloth; illustrated. Longmans, Green & Co., New York, Publishers.

VORLESUNGEN ÜBER FRAUENKRANKHEITEN. By Dr. KARL ABEL. 583 pages; illustrated; price 14 M. Oscar Coblentz, Berlin, Publisher.

Rev[illegible] Medicine. By Ch Bouchard, A. Chauffard, A. Chauveau, L. Landouzy, R. Lépine, A. Pitres, H. Roger and L. Vaillard. 891 pages. Librairie Felix Alcan, Paris, Publishers.

The Bacillus of Long Life. By Loudon M. Douglas, F.R.S.E. 103 pages; illustrated; cloth; price $1.50. G. P. Putnam's Sons, New York and London, Publishers.

Developmental Pathology. By Eugene S. Talbot, M.S., D.D.S., M.D., LL.D. 435 pages, with 340 illustrations; cloth. Richard G. Badger, Publisher, Boston.

Transactions of the American Gynecological Society for the Year 1911. Vol. 36. 605 pages, cloth; illustrated. Wm. J. Dornan, Publisher, Philadelphia.

Aids to Histology. By Alexander Goodall, M.D., F.R.C.P. 130 pages; cloth; price 2/6 net. Ballière, Tindall & Co., Publishers, London.

Scientific Features of Modern Medicine. By Frederic S. Lee, Ph.D. 183 pages; cloth. The Columbia University Press, Publishers, New York.

L'Internationalisme Scientifique. By P. H. Fijnman. 108 pages; paper. Bureau Préliminaire de la Fondation pour L'Internationalisme, Publishers, La Haye.

Nervous and Mental Diseases. The New Seventh Edition. By Archibald Church, M.D., and Frederick Peterson, M.D. 932 pages, with 338 illustrations; price, cloth, $5.00 net; half morocco, $6.50 net. W. B. Saunders Company, Publishers, Philadelphia.

Diseases of the Digestive Canal. By Dr Paul Cohnheim. Translated by Dudley Fulton, M.D. 383 pages; illustrated; cloth; price $4.00. J. B. Lippincott Company, Publishers, Philadelphia and London.

Diagnose und Fehldiagnose von Gehirnerkrankungen aus der Papilla Nervi Optici. By Prof. Dr. Fr. Salzer. 10 pages; illustrated; paper; price 1.50 M. J. F. Lehmann, Publisher, München.

Uber Neurorezidive nach Salvarsan und nach Quecksilberbehandlung. By Dr. J. Benario. 105 pages; paper; price 1.50 M. J. F. Lehmann, Publisher, München.

The Diagnosis of Nervous Diseases. By Purves Stewart, M.A., M.D., F.R.C.P. 477 pages; illustrated; cloth; price $4.50. E. B. Treat & Company, Publishers, New York.

Medical Record Visiting List for 1912. New Revised Edition. William Wood & Company, Publishers, New York.

Dieterichin og Xanthonin. By Mentz von Krogh. 80 pages; paper. Trykt I. Steen'ske Bogtrykeri, Publishers, Kristiania.

Die Gonorrhoe des Mannes. By Dr. Wilhelm Karo. 100 pages; paper; price 2.80 M. Julius Springer, Publisher, Berlin.

Des Fractures du Rachis Cervical sans Symptomes Medullaires. By Jules Boecker and André Boeckel. 218 pages; illustrated with 20 plates; paper; price 8 fr. Librairie Felix Alcan, Felix Alcan et R. Lisbonne, Publishers, Paris.

Handbuch der inneren Medizin. By Prof. Dr. L. Mohr and Prof. Dr. R. Staehelin. 1077 pages; illustrated; paper; price 20 m. Julius Springer, Publisher, Berlin.

Studies from the Rockefeller Institute for Medical Research. Vol. XIII. 322 pages; paper. The Rockefeller Institute for Medical Research, Publishers, New York.

Traité de la Blennorrhagie et de ses Complicataons. By Dr. Georges Luys. 550 pages; illustrated; paper; price 12 francs. Octave Doin et Fils, Publishers, Paris.

Syphilis. By James McIntosh, M.D., and Paul Fildes, M.B., B.C. 227 pages; illustrated; cloth. Longmans, Green & Co., Publishers, New York.

Untersuchungen über die Strickleiter der Blutzellen. By Dr. Alfred V. Decastello and Dr. Alexander Krukoff. 110 pages; illustrated; price $4.00. Rebman Company, Publishers, New York.

Die experimentelle Bakteriologie und die Infektionskrankheiten mit besonderer Berücksichtigung der Immunitätslehre. By Dr W. Kolle and Dr. H. Hetsch. 968 pages; illustrated; paper; two volumes; price, complete, $8.50. Rebman Co., Publishers, New York.

Lehrbuch klinischer Untersuchungsmethoden. By Dr Theodor Brugsch and Dr. Alfr. Schittenhelm. Second Revised Edition. 712 pages; illustrated; paper; price $4.25. Rebman Company, Publishers, New York.

Die Methoden der Untersuchung des Magens und ihre diagnostische Verwertung. By Dr. Emil Schutz. 240 pages; illustrated; paper; price $2.75. Rebman Company, Publishers, New York.

A Manual of Physiology. By H. Willoughby Lyle. 747 pages; illustrated; cloth; price $4.00. Oxford University Press, Publishers, New York.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended December 30, 1911:

	Cases	Deaths
Tuberculosis Pulmonalis	405	149
Diphtheria	309	36
Measles	421	7
Scarlet Fever	217	8
Smallpox	1	1
Varicella	134	—
Typhoid Fever	64	9
Whooping Cough	14	—
Cerebrospinal Meningitis	2	4
Malarial Fever	—	—
Totals	1,567	214

The Effect of Paludism on Pregnancy, Labor and the Puerperal State.—Laffont finds that malarial fever has a marked effect throughout and after pregnancy. It may be transmitted from the mother to the fetus. Abortion or premature labor is very likely to result. Fetal paludism is proven by finding the parasites in the fetal blood. In some cases it produces deformities of the fetus; in most cases the child is weak and underweight. Hereditary paludism may be latent for some months, or may at once produce characteristic paroxysms. It is more likely to be transmitted during the last three months of pregnancy. If it is to recur in the mother after labor it will generally appear within ten days; it may cause hemorrhages either at or after labor. There is inertia uteri and artificial delivery is often necessary. The disease may become pernicious in the mother, though as a rule its course is benign. The secretion of milk is modified and may be suppressed; it does not transmit the parasite. Malaria following labor is not generally typical in form. Quinine is the best treatment for it.—*L'Obstetrique.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended December 29, 1911:

Places	Date	Cases	Deaths
CHOLERA			
Bulgaria: Douvlare	Nov. 14	1	..
India: Madras	Nov. 19–25	82	65
Indo-China: Saigon	Oct. 29–Nov. 5	2	2
Italy		..	..
Total Nov. 19 to 25: Cases 77, deaths 39			
Provinces: Caltanisetta	Nov. 19–25	7	1

THE MUSICAL MEMORY AND ITS DERANGEMENTS (AMUSIA).

By J. LEONARD CORNING, M.D., LL.D.,

NEW YORK.

THE literature dealing with derangements of the musical memory is extremely limited; only within the last few years has the subject received anything like the attention it deserves. It is difficult, at first thought, to assign adequate grounds for this neglect. On reflection, however, it would seem that the fact that so few persons enjoy a thorough musical education must have a great deal to do with it, for only in individuals of this restricted class who are sufferers from cerebral lesions is it possible to study such phases of amusia as "musical agraphia" and "musical alexia." When, however, due allowance has been made for this circumstance, and even for the fortuity that few musicians are psychologists and not all psychologists are musicians, there still lingers the suspicion of unaccountable neglect. This suspicion deepens, moreover, into certainty when one enters upon the study of the normal musical memory, as it reveals itself in the achievements of great artists or accomplished amateurs. Where is a comprehensive statement of the psychology underlying these undertakings to be found? Certainly if such an account exists, the writer has not been able to track it.

In the present paper an attempt has been made to supply this last-named deficiency, as far as may be, and at the same time to give a description of those disorders of musical recollection commonly grouped under the term "amusia." If, at times, the matter introduced shall appear somewhat trite to the initiated, the writer begs to urge in extenuation his desire to make himself intelligible to those who, whether from choice or lack of opportunity, have failed greatly to concern themselves with things psychological.

General Considerations.—The musical faculty, as is well known to those who have given much attention to the psychology of childhood, is developed very early. In many children the tone-images arise before the word-images. Thus Reger (cited by Edgren and others) reports the case of a child nine months old who could accurately repeat a series of notes previously struck on a piano, while Stumpf relates the history of a precocious child of fourteen months who could sing a scale from end to end without a mistake. The case of the composer Dvôrák's son is well known. This child was able to sing the "Fatiniza" march with his nurses when but one year old. Six months later he could sing the melodies composed by his father, while the latter accompanied him on the piano. Examples of prodigious musical memory are likewise found among children of a somewhat later age. What are the psychological processes underlying such feats of musical recollection, whether displayed by the old or the young, the instrumentalist or the vocalist? Some preliminary acquaintance with the processes underlying memory in general is necessary to an adequate answer. In the first place it is necessary to remember that, despite the fact that the usages of common speech imply that memory is, as it were, an autonomous faculty, there is no ground whatever in physiological psychology for any such assumption. On the contrary, as Volkmann long since pointed out, "there are as many species of memory as there are species of representation." Thus, there is a memory for visual impressions and another for auditory impressions. There is likewise—and this is of especial importance in connection with the subject of this paper—a memory of our various motor experiences, including those concerned in voice production and the manual arts. Again, within the scope of a single sense there are differences of memory: memory for articulate sounds differs from the memory for musical sounds; the memory for form from that for colors. Nor are the memories of all the senses equally good: those senses possessing the greatest discriminative refinement disclose the best memories. Hence what one has seen or heard—sight and hearing being endowed with great discriminative power—is best remembered (memory of reproduction); while next come the memories of touch, taste, and smell, which indeed are sharply awakened only when the stimulus which gave rise to them is re-presented (memory of recognition). Speaking generally, it is obvious then, from what has been said, that there are as many kinds of memory as there are mental activities concerned in knowing. Further, it is a matter of common experience that individuals differ greatly in their capacity of remembering; so that one hears this person spoken of as possessing a good memory for "poetry or music," that one for "abstract thought," and so on. What is not so commonly appreciated is that persons differ not a little in their ability to recall tactile impressions and coordinated movements, whether coincident or sequential, and that this fact is largely responsible for the varying degrees of dexterity or clumsiness disclosed by manual workers of all kinds.

The Rôle of Association in Memory.—The important part played by the "association of ideas" in the process of remembering is familiar to most persons. The recollection of the face of a bride we once saw at a wedding recalls the color of the flowers she wore; an odor recalls the flower of which it is an attribute, or it may be the personality of a lady who wore it at a ball years ago. The examples are legion; every one can recall them.

For purposes of convenience most authors classify associations into those of contiguity and those of similarity. Association by contrast, convergent association, and "obstructive association" are discussed by some writers. By contiguous association the parts of our more or less complex experiences occurring at a particular time or place tend to suggest each other, and this irrespective of any qualitative unifying principle between the parts. In association by similarity, on the contrary, the likeness or similarity of the parts determines the cohesion. Both kinds of association may take place spontaneously, and they may likewise be arbitrarily initiated by the will and intensified by interested attention and repetition.

Three stages of memory are commonly spoken of by writers on psychology; these are retention, reproduction, and recognition. By "retention" it is not to be understood that images, perceptions, and thoughts are hoarded—"stored away" in the convenient but misleading language of every day; but rather that these processes leave such cerebral traces as, under proper conditions (notably suggestion), make reproduction possible. And, further, the well-known tendency of the mind to act again and again in the same manner, a tendency enhanced by habit, repetition, and interest, affords an additional clue to the *modus operandi* involved.

Two kinds of recognition have been differentiated—immediate and mediate. If one meet a friend and from the familiar appearance of his face recognize him to be Jones, the mental process involved is one of "immediate" recognition. If, on the contrary, one select from a number of watches closely resembling each other the one bearing the initials "C. E. R.," perceiving from these markings that the watch is one's own, the process is one of mediate recognition. Clearly, then, recognition as a whole is an instance of association by contiguity. "But why," it may be asked, "is C. E. R." more mediate than face? In reply it may be remarked that "face" is part of Jones, a natural associate, indeed, in the fullest meaning of the word; while "C. E. R." is a fortuitous label, a signal agreed upon, having nothing whatever to do with the inherent nature of watch.

Neither the purpose nor the limits of the present writing permit a discussion of the purely controversial questions of memory, notably those that have been raised in connection with the principle of "similarity." For the benefit, however, of those who may be interested the writer would refer to the publications of William James, and notably to the chapter on "Memory," contained in the first volume of his "Principles of Psychology."

The Musical Memory.—From the foregoing sketch, brief though it be and unavoidably summary in many particulars, the writer is fain to hope that the reader uninformed in matters psychological is in some sort prepared for the discussion of acquisition, retention, and reproduction—memory, in short, as we find it disclosed in connection with the art of music, instrumental and vocal alike.

Three kinds of images, auditory, motor, and visual, are largely concerned in the musical memory. True, their importance is unequal, the auditory representations ranking first, while the motor and visual ones come after. Again the motor and visual representations are by no means of the same importance in all persons; nor, it may be observed, does the acquisition of the motor representations present the same difficulties in the vocalist as in the instrumentalist.

Besides the auditory, motor, and visual representations there are other elements that signify much to the musical memory. Of the very first importance in this respect are the sense of time, rhythm, melody, and harmony. Time, as exemplified in the musical bar, and rhythm are often confused. "The bar is the division of a musical work into parts which all have the same duration; rhythm is constituted by a division of quite another kind, superposed upon the preceding and giving to the parts of the composition durations *which are not necessarily equal.*"[1].

Time is a mechanical formula; rhythm a product of the esthetic.

When one listens to a series of monotonous sounds they presently seem to arrange themselves into groups of twos or threes or fours and sixes. On attempting to discover (without counting) how many clicks of a metronome may be apprehended as an unitary idea, it will be found that as many as forty-eight are capable of this fusion, provided that the individual clicks follow each other with sufficient rapidity to insure that the whole series shall occupy less than twelve seconds.

Stoddart[2] has elucidated this fact in the following perspicuous language: "Now if at any time we endeavor to think of the present moment in contradistinction to the past or future, we find that it is gone before we have had time to think. The present is always immeasurably short; it is indeed nothing but a moving boundary line separating the past from the future. Now, as a matter of experience, we include in our practical cognition of the present a short period of the immediate past. The existing unit of time, as thus conceived, has received the name of the "specious present," and the metronome has taught us that such an unit may be as long as twelve or even fourteen seconds. These units are not separate from one another, but perpetually and constantly overlapping. . . . .

"Inasmuch as we are unable to give a name to each such 'perceptual unit,' any given unit is identified with some incident (psychologically speaking, with some percept). . . . . And when a mother tells us that a certain event took place 'the year that Willie was born,' she is making an abstraction from the Willie's-birth idea.

"The point I wish to emphasize is that the temporal relations of a percept are an essential part of the percept itself; and similarly the temporal relations of an idea are an essential part of the idea. In the case of a percept, there is always a feeling of 'now-ness'; and in the case of an idea, the revival of a specific percept, there is a feeling of 'then-ness.'"

In musical memory the temporal relations are identified with auditory and motor representations, particularly the latter; and this, while especially true of the instrumentalist, is also true of the singer.

The specific objects of the present writing do not permit the discussion of the various speculations as to the evolution of the sense of time and rhythm that have appeared from time to time in periodical literature. For the benefit of those who are interested the writer refers to the previously quoted work of Combarieu[3], wherein the whole question is briefly but suggestively treated, and to Bücher's[4] interesting monograph on the relation of work to rhythm (time).

As may readily be imagined, both melody and harmony, particularly the former, are of great as-

sistance to both acquisition and reproduction. Melody, generally speaking, is the significant, agreeable succession of a number of notes; harmony the agreeable correspondence of two or more notes sounded together.

Quite irrespective of the theoretical elements entering into its structure, which cannot be dealt with here, melody has that musical meaning "which it bears within itself." The composer "has given it a significance which we should seek in vain to express by words, and which, although only to be reached through the musical sense, has for it perfect clearness." This is no mere metaphysical figure of speech. Listening to a song one distinguishes it from an unmeaning formula; and this may be done by a person unacquainted with the theory of music, as well as by the most sophisticated student of the art. Melody, then, "says" something, yet to venture a verbal translation is scarcely less than an impertinence.

Another peculiarity of melody is that it is remembered, that it obtains a lodgment in memory that time and vicissitude are often powerless to efface; while mere academic sequences or even highly colored, but incoherent effects leave no souvenir. Polyphonic ingenuity of a high order, coupled, however, with amazing melodic sterility, is a characteristic of certain modern compositions; and hence, while the immediate sensuous appeal of such music is often undeniable, it is as refractory to recall as the disconnected verbiage of a band of inebriates.

Melody, then, is the vehicle *par excellence* of musical sense, if one may so phrase it; and its presence, by virtue of this attribute, is an aid to recollection of the first magnitude.

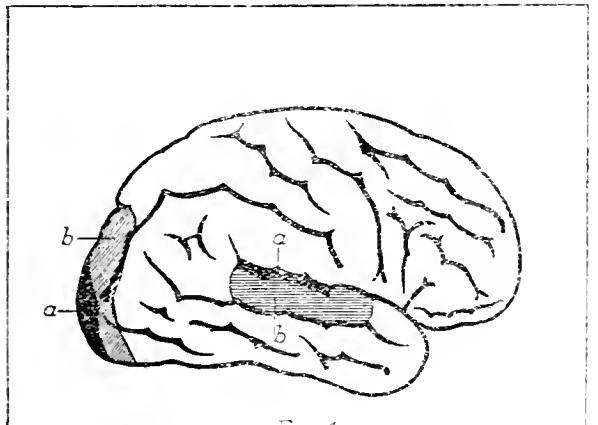

Fig. 1.

Fig. 1.—Visual and auditory centers (Campbell). Occipital lobe: *a*, Primary visual center; *b*, visuo-psychical area. Temporal lobe: *a*, primary auditory center; *b*, audito-psychical area.

Cortical Auditory and Visual Centres.—While it has long been believed that the cortical auditory center lies in the superior temporal convolution, recent researches, more especially those of Campbell[5], seem to point to the posterior end of the superior surface of the first temporal gyrus *within* the Sylvian fissure as the primary auditory center, or center for the reception of simple auditory impressions. It is, moreover, assumed that this auditosensory center is, to an extent, surrounded by an auditopsychical center, located, as Campbell believes, in the cortex of the convexity of the posterior end of the first temporal convolution. Lesion of this auditopsychical area (speech center) is followed by word-deafness: the subject loses the power of recalling names and words and of interpreting spoken language; yet simple auditory sensation remains—the subject hears what is said to him, but cannot comprehend. In right-handed persons this center is situated on the left side of the brain and is provided with a number of subcortical connections. The most significant of these are the fasciulus longitudinalis superior by which it is brought in relation with the inferior frontal gyrus, and the fasciculus longitudinalis inferior, which connects it with the primary visual center.

The cortical half-visual or visuosensory center occupies, according to several investigators, the cuneus, the lingual lobe, and a portion of the external aspect of the occipital pole. A psychovisual center, occupying the external surface of the occipital lobe and a portion of the cuneus, has been recognized by a number of writers, Campbell among others. Fig. 1 shows the primary visual center, the visuopsychical area, the primary auditory center, and the auditopsychical area. The occipital lobe is in intimate relation with various other portions of the brain. One such relation possesses peculiar interest—that with the temporoangular region by means of the inferior longitudinal fasciculus; for it is the angular gyrus with its subcortical longitudinal fasciculus and the second occipital gyrus that are concerned in the recognition of printed or written language. Destruction of this region—the angular gyrus more especially—gives rise to "word-blindness"—alexia. For an explanation of the coexistence of "subcortical" alexia with hemianopsia the writer would refer to the textbooks.

Cortical Motor Areas.—As all are aware, the cortical motor areas are situated in front of the fissure of Rolando and comprise the precentral or ascending frontal convolution and the anterior wall of the fissure as well. Immediately anterior to this region is the "intermediate precentral area" of Campbell or psychomotor area, which is held to preside over the more highly specialized movements, notably writing and articulatory speech (and probably also over the movements involved in playing upon musical instruments). The precentral area, on the contrary, presides, according to current notions, over the coarser movements only.

Cortical Sensory Areas.—The sensory areas of the cortex occupy the ascending and superior parietal convolutions. The postcentral convolution, situated immediately behind the fissure of Rolando, has been separated into a primary sensory and a psychosensory portion, the former lying in and immediately behind the fissure; the latter in close connection with the superior parietal lobule.

There is evidence—largely clinical—to show that the postcentral convolution is the cortical area for tactile localization and discrimination, and the same may perhaps be said, to some extent at least, of temperature and pain sensations. The primary recognition of sensations of passive and active movements has also been imputed to this gyrus. A further, and perhaps higher, representation of sensations of touch (localization) and of those of active and passive movements has been ascribed to the region posterior to the corresponding motor areas and structurally associated with them. The motor and sensory areas of the brain, according to Campbell, are shown in Fig. 2.

Plausible as it seems in some of its factors, the above résumé of cortical sensory functions cannot as yet be regarded as adequately established. Impartiality indeed compels the admision that, despite

the excellent work already accomplished, many data are still required to render it immune from logical assault. For the time being, however, and for the purposes of the present writing more particularly, it serves an excellent purpose in giving, as it were, pictorial definitness to psychological discussion, a matter of some moment to those who have little vocation for abstract thinking.

The importance of motor representations to the instrumentalist has already been indicated. The sense, and hence the memory, of position and movement is, however, derived not from a single source, but from a number of sensations. Chief among these are muscular, tendinous, and articular sensations; and, insofar as delicacy of adjustment is concerned, those of touch must also be considered. Just now there is a tendency to discern predominant significance in articular sensations, due largely to the experiments of Goldscheider, who has been able to show that, when a joint is rendered anesthetic, movements, whether active or passive, are rendered much less perceptible. Wishing to determine for himself the relative importance of tactile impressions to the psychological mechanism concerned in playing on an instrument, the writer of this paper covered the tips of his fingers with a thick coating

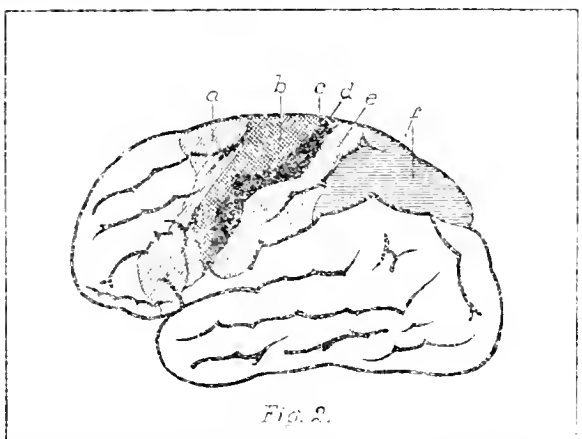

Fig. 2.

Fig. 2.—Motor and sensory area of the brain (Campbell). *a*, Intermediate precentral area; *b*, precentral area; *c*, fissure of Rolando; *d*, postcentral area; *e*, intermediate postcentral area; *f*, parietal area.

of collodion. When thus deprived of the orientation usually derivable from the sense of touch he observed the following: (1) that he could still play, after a fashion, from note, and (2) from memory, as well, but that (3) his playing had lost all delicacy, the fingers hobbling clumsily, as it were, over the keys, with which all sensory intimacy had been broken. This is a simple experiment which any one can repeat.

Resuming the psychological phase of the discussion, let us consider memory as manifested in the instrumentalist first. A question which will naturally occur to one on the threshold of an investigation of this kind is, "How do instrumentalists who are in the habit of playing without the aid of notation commit to memory the most elaborate compositions? What is their method? How do they proceed? While there is a general resemblance in methods, certain deviations are discernible as between the musicians themselves and, indeed, to some extent, in the same musician at different times and under varying circumstances.

The following are the principal varieties of association which the writer has been able to make out in musicians who are in the habit of committing to memory more or less of what they play:

A. Predominant association of the auditory and motor memories.

1. The auditory memory is better than the motor (finger) memory.

2. The motor memory is better than the auditory memory.

B. Predominant association of the visual and motor memories.

1. The visual memories are somewhat better than the motor ones.

C. Association of the auditory, motor, and visual memories.

1. The auditory-motor association is the stronger, the visual memories being less vivid, more loosely associated, and consequently playing but a supplementary or intermittent rôle in the process of reproduction.

2. The cohesion of the auditory and motor memories is less firm, as disclosed by inability to execute certain passages without the supplementary aid of visual memory.

It will be well to consider these various phases of the musical memory somewhat more in detail; and, in so doing, we shall be helped not a little by studying the methods of acquisition ("committing to memory") followed by persons who afford typical illustration of the varieties of musical memory as distinguished and tabulated by the writer. Let us take, then, the individual in whom the auditory and motor memories are predominantly associated and whom we have classified under A, 1.

The writer once had the pleasure of knowing a violinist, in his younger days a celebrity of international repute, who affords a good illustration of this type of musical memory. When committing to memory a piece which he purposed playing in public, this artist proceeded about as follows. He would place the notes on the music stand, and having played the piece through several times put his violin aside and endeavor thereupon, or later while walking or driving, to recall, if not all at least the chief features of the composition in the order in which they were set down. When questioned as to whether he was aided in this by remembering the notes, he answered in the negative, declaring that very few of them loomed in his mind, and that the process up to this point was purely one of auditory memory. His next step consisted in playing from the beginning each phrase again and again until he could play the entire piece through without a fault. This method, with slight modifications, is the one frequently followed by musicians, the finger (motor) memory being acquired in association with the auditory memories.

A still more striking illustration of the auditory motor memory is frequently met with among certain amateurs to whom musical notation conveys little or nothing, and who play everything "by ear." Such persons on returning from a concert or the opera are able not only to remember much of the music they have heard, but, what seems still more remarkable, immediately to play it with astonishing accuracy.

Truly the auditory memory here displayed is remarkable, yet not more so than the natural cohesiveness between the motor and auditory memories implied by such achievements; for it is a noteworthy fact that the individual himself does little or nothing in the way of practice to promote and maintain such association. Of those cases of auditory-motor memory, in which the motor memory exceeds in efficiency that for sound (A, 2), it

may be said that the most striking examples are usually found among children, who, disclosing neither pronounced love nor any considerable aptitude for music, are nevertheless spurred on by their parents or teachers to study some instrument, usually the piano. Though such pupils are often strikingly lacking in ability to recall melodic sequences even the most obvious, they attain ultimately, by dint of much exercise of the fingers (motor memory), to the execution of pieces impossible to those inherently much more musical, but in whom the motor memory is naturally deficient or imperfectly developed. The writer has often seen children of this kind clap down before the "clavier" (dumb piano) and, disdainful of the notes, play long and difficult pieces from beginning to end without a shadow of hesitancy. Thus there could be little or no assistance from auditory association, the instrument being voiceless and the subject's recollection for musical sequence of the slightest. Needless to say that the effects obtained by persons of such one-sided endowment are highly mechanical and innocent, quite, of musical expression.

Very interesting is the type of musical memory in which the visual and motor memories are predominantly associated (B). Musicians in whom this kind of memory is in the ascendant declare that they are able to "see the notes" as vividly almost as though the printed page were spread out before them. Their method of "committing" to memory differs from that described under A, inasmuch as their attention is largely though not wholly given over to remembering the appearance of the printed notes rather than the sounds proceeding from the instrument. In this phase of musical recollection the visual and motor memories are sometimes of about equal efficiency. More often, however, the visual memory is decidedly the better, a fact of which the musician himself may be fully aware.

Finally we have the third type of musical recollection—that in which the auditory, motor, and visual memories are more or less prominently concerned (C). A striking instance of this type of musical memory was exemplified by a certain musician of note, who informed me that when playing as a soloist he was able simultaneously to recall, visually and acoustically, every note of even the longest composition, while at the same time he was acutely aware of the variations in sensation accompanying the myriads of muscular movements—"had the feeling of the fingers," as he graphically expressed it.

As may readily be supposed, the three kinds of memory here associated are not equally well developed in most musicians. Sometimes the auditory motor association is the strongest, only a few of the more important notes being visualized (C, 1). Again, but more rarely in really good musicians, the cohesion of the auditory and motor memories seems lacking in firmness, and this despite prolonged and earnest practice. Under these circumstances recourse is had to the visual memory to piece out, as it were, what is lacking in the others (C, 2).

Critical Observations on the Various Methods of Committing to Memory Commonly Employed by Musicians.—From what has already been said, it will be evident to most persons of intelligence—and more especially to those who, having some knowledge of psychology, possess at the same time a practical acquaintance with instrumental music—it will be evident to those possessed of this dual equipment that these various types of memory and the different methods of committing to memory associated therewith cannot be of equal value in so far as reliability, smoothness, brilliancy, and expressiveness of execution are concerned. Various questions will at once occur to one. Take the matter of association: is a predominant auditory-motor, or an auditory-visual, or an auditory-visual-motor association to be given the preference? Speaking from the standpoint of theory as well as from a somewhat extensive personal experience, the writer would unhesitatingly award the primacy to the auditory-motor type of memory. Here the translation of the auditory representations into action and sound is immediate, whereas, when the printed notes are remembered, the translation is more indirect, viz., from a visual representation to action and so to sound. Nor is this all. The visual representations of the printed notes, even when coexisting with fairly developed auditory-motor memories, tend to act as disjunctive associates, more or less, and they do this by causing a division or shifting of attention (obstructive association) both in committing to memory and in reproduction, so that sometimes the auditory-motor representations are firmly knit; at others, the visual-motor ones. Attention, indeed, when properly managed makes possible feats of musical recollection that to the uninitiated seem little short of the miraculous. But attention itself—a fact but too often disregarded—is an exceedingly complex affair. Interest, direct or indirect, natural or artificial, is the price exacted for its keenness and its duration. This implies that the genesis of attention is to be sought in emotion, and such analysis will show to be the case.

Two phases of attention are commonly recognized. These, "spontaneous or natural" and "artificial or volitional," have already been mentioned. Spontaneous or natural attention is aroused by the interest inherent in the subject. Artificial or volitional attention, on the other hand, is maintained by interest, indirect, remote, as when an otherwise disagreeable task is performed for the sake of ambition, good to others, and so forth. The number of such incentives is legion, and many will occur to everyone. As frequently pointed out by those who, like Ribot, have made special studies of attention, the spontaneous or natural variety is essentially that of the primitive races, while the artificial or volitional type has been evolved through the process of civilization. That physiological conditions have much to do with the efficiency of both memory and attention has long been known. Without particularizing, it may be stated as a general truth that any pathological condition giving rise directly or indirectly to impairment of cerebral nutrition as a whole and cortical nutrition in particular may be followed, and usually is followed, by derangement of memory and attention, more or less. The same may be said of the abuse of alcohol, tobacco, and indeed of the whole group of narcotics, whose effects on both retention and reproduction are of the worst. On the other hand, it is a noteworthy fact that certain narcotics, when taken in small, stimulating doses by those not given to their abuse, facilitate the whole process of musical reproduction though not that of acquisition ("committing to memory"). This applies with special force to cases of cerebral debility from whatever cause arising. The practical utilization of this fact in the management of certain derangements of the musical mem-

ory is, of course, entirely admissible, but for obvious reasons is not otherwise to be recommended.

Attention, then, is of the very first importance to the musician who would have at command a répertoire, even a restricted one.

When committing to memory lengthy and difficult compositions, one should endeavor to relieve the tedium and monotony of the process by suggesting constantly to oneself the pleasure and benefit ultimately to be derived—the freedom of interpretation; the exhilaration of playing so long a piece without the aid of the printed notes; the sensuous charm of the music itself; the scientific interest of the process of memorizing, etc., etc. In this way interest, and hence attention, may best be maintained. A further and extremely important point is the avoidance of anything approaching excessive fatigue. To this end one should pause frequently for rest. Due allowance being made for differences of aptitude, the writer would hazard the suggestion that from fifteen to twenty minutes is about the average length of time during which the process of memorizing may be uninterruptedly carried on to good effect. Thereafter a pause of ten minutes; then to the task again, and so forward. As committing to memory is exhausting work even at the best, probably most persons will have had all of this

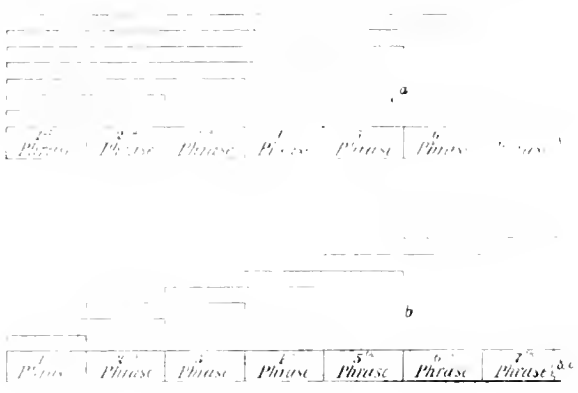

Fig. 3.

kind of exercise they care for at the end of an hour or two. In young persons, when interested and properly directed, the process is a shorter and an easier one than in those of middle age; and the like may be said of those exceptionally endowed. The mode of progression in musical memorizing is not a matter of indifference. In the first place the musical phrase should be taken as the unit and not the measure, as is frequently and ignorantly done. The tempo should, in the beginning, be a slow one, but not so slow as to interfere with the rhythm, the correct observance of which assists the process of retention. Beginning with the opening phrase, the musician will repeat the same a number of times, paying, meanwhile, the closest attention to the melodic sequence and the *sensations* accompanying the different movements of the fingers. This done, he will close his eyes, or turn from the notes, and endeavor to play the phrase by memory only. Having succeeded in this, he may take up the next phrase and so forward, always repeating, however, before taking up a new phrase, much or all of what has gone before. (Fig. 3, *a*.) In compositions of great length, however, this will hardly be possible, and some such modification as that indicated in Fig. 3, *b*, may be adopted.

The effect of this will be to establish a continuous and durable association, both in a melodic and motor sense, from beginning to end. True, the phrases occurring first will have received more attention, will have been more frequently repeated than those that follow; but this can later be compensated for by practice. Meanwhile, as already intimated, a fairly cohesive bond has been established as well between the phrases themselves as between the motor and auditory images. Association is, in fact, well initiated, but to make it durable will necessitate much additional effort. What is the state of consciousness during reproduction at this time? Retrospection, according to the experience of the writer, will help to an answer better than introspection, the affective elements involved being too illusive for the latter mode of inquisition. The most prominent element of consciousness while "playing from memory" at this stage of acquisition is undoubtedly the intense awareness, the keen attention, the latter being directed, in part to the melodic sequences, in part to the motor memories ("the feeling in the fingers"), and finally, but in less degree, to the visual memories of some of the printed notes. Despite this exaggerated condition of attention, mistakes occur, especially while rendering passages involving unusual or awkward fingering; and, as an inevitable consequence, elegance of execution and expressiveness are conspicuously wanting. Not until much subsequent practice has wrought a change in the character of the reproductive process does the playing of the musician take on a really artistic quality. This change is brought about by the conversion of a process till now largely voluntary into one essentially automatic.

The Automatic Element as Disclosed in the Musical Memory.—The more frequently a mental operation is consciously and attentively performed, the more does it tend to repeat itself, and the less are attention, volition, or consciousness necessary to such repetition. Thus it comes to pass that while actions involving delicate motor coordinations like sewing, swimming, and various other feats of skill were during the time of their acquisition volitional in character, consciousness and attention being of the keenest, these same actions, by dint of much repetition, have ultimately become independent of voluntary control, and are performed unconsciously—"automatically," as the books phrase it.

This is the phenomenon that is predominantly in evidence in what may justly be regarded as the second stage of the acquisitive process, as any one accustomed to play from memory may readily convince himself.

While this transformation of the volitional stage, of the stage of vivid consciousness of the motor and auditory memories, of the period of tense attention—while this transformation of a volitional into an essentially automatic process may be thus made out, it would be a gross error to imagine that there is anything of a sudden nature in such transition. On the contrary, the process is a gradual one, consciousness of the movements more especially declining progressively in vividness as these (the movements), impelled by constant repetition, assume an ever increasing automatic character. The accompanying diagram (Fig. 4) should help to an appreciation of the transformation wrought in the character of the motor element. The movable hand represents the musical memory. The + and — signs are used to indicate the increase or decline of the conscious, or automatic, element. By causing the hand to revolve about its axis the decrease of consciousness and the increase of automatism may be shown. Turning it

in the opposite direction causes the reverse to become apparent.

Supplementary Observations.— There are several features of the musical memory which it has seemed best to consider at the end of the discussion rather than earlier, as what has gone before cannot fail to

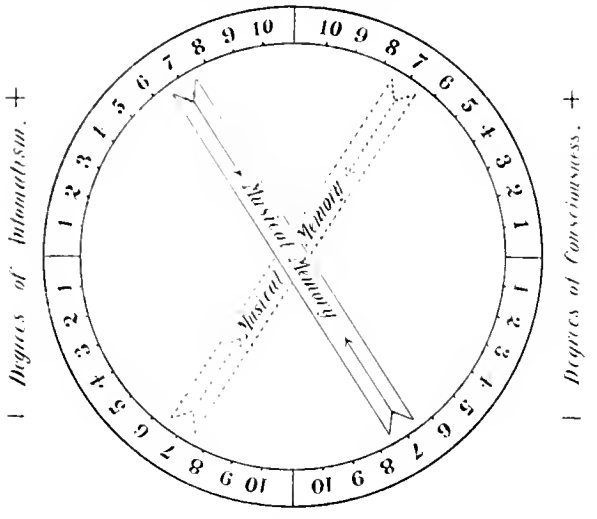

Fig. 4.

help to their fuller appreciation. Of practical interest, in this connection, is the fact that the tendency to pause is almost, if not quite, as strong as the tendency to act. This is shown in various ways, but in no wise more strikingly than in the first playing of difficult passages. These when suddenly encountered are apt to give rise to an involuntary relaxation in tempo, amounting sometimes to an actual pause. But a few repetitions are sufficient to confirm the habit, which is not only an artistic blemish but a difficulty not easily overcome. The formation of such a habit may be entirely avoided by beginning practice not at the beginning of the difficult passage, but a phrase or two before it, the whole being played in a scrupulously regular but considerably slower tempo. Even more disconcerting is the "question." Let an instrumentalist ask himself while playing, "Is it 'flat' or 'sharp'?" and in a twinkling his discomfiture is complete. Even in the slower movements there is no time for the balance of this and that; and, moreover, as may readily be conceived, the sudden introduction of a process so elaborate as that involved in judging is of itself sufficiently disjunctive to disrupt the whole mechanism of association. For the rest, the name of the note is not the thing to be regarded either in acquisition or reproduction. What the attention should fasten on during acquisition and continue to hold to until automatism completely asserts itself, is *sensation*, sensation of movements and of sounds—coincident, as in accords; sequential, as in melody, florid passages, etc. From this it is to be understood that the strain of attention is *inward*, as in ordinary remembering, not outward, as when, for example, one observes an ordinary after-image. Failure to appreciate these facts is undoubtedly responsible for much bad teaching.

The playing of scales and cadenzas and, indeed, all instrumental performances involving sureness, rapidity, and the technical accomplishments which these imply have always evoked the admiration and astonishment of the uninitiated. Yet the difficulties, assuming the artist to be a master of the auditory-motor method of memorizing, are by no means what they seem. The explanation of this almost infallible fluency resides in the fact that, automatism being fully established, not only does each note "suggest" its successor, but, as it were, *compels* it. How strongly knit, how refractory to intrusion, is musical association when fully established is easily demonstrated. Let an attempt be made while playing rapidly to eliminate a note or introduce a new one, and in a twinkling the selfpossession of the player is gone and he fumbles helplessly. Nor is this all. Let the player place the printed notes before him, and writing in the notes which it is sought to introduce, or striking out those which it is desired to eliminate, proceed to play the florid passage at a much reduced tempo. To his astonishment, perhaps, he will find that when thus substantially assisted, as it would seem, by the printed notes and a reduction of speed, he still tends to hesitate and fumble, being aware at the same time of certain disagreeable sensations, none the less real because hard to describe.

In playing rapid passages, one is aware, moreover, of a feeling of being, as it were, swept forward, compelled, pushed, in short, to a kind of sequential gymnastic (avalanche affect), the individual steps of which are no longer clearly appreciable, since they are amalgamated or fused into what seems a new and inclusive sensation. "Suggestion" is a weak word to explain a happening so obviously dynamical; but if, when employing it, it be understood to imply that in the original process of acquisition certain changes were wrought in the central nervous system, changes which alike made possible predetermined, orderly association, retention, and reproduction—if the word be used in this sense, it may be accepted, *faute de mieux*, in deference to the vogue long enjoyed by it. The appended diagram (Fig. 5) will help to an appreciation of what the writer would imply by this dynamical experience (avalanche affect) as conspicuously manifested in rapid playing, the intervals being short, and the music consisting largely of scale-like passages or runs.

Fig. 5.—Graphic aid to the appreciation of the dynamic element disclosed in rapid playing. The diagram assumes that a rapid passage has just been played, and suggests the compelling force successively exerted by each note upon the one immediately following. Thus the initial impulse (first note) to 2, 2 to 3, 3 to 4 and so forward.

The phenomenon of automatism as it concerns the musical memory having been discussed in considerable detail, we are now in a position to propound a question which, so far as the writer is aware, has nowhere been either put or answered. We have already seen how by dint of attention and much repetition the more voluntary phase of memory assumes an increasingly automatic character. Now, assuming that the playing of a certain musical composition has become automatic, so automatic, in fact, that, as sometimes happens among pianists, the musician is able to play it while carrying on a desultory conversation—assuming this, what happens if an attempt be made to reverse the process, to play in a voluntary manner, as during the process of acquisition, attention being alert to the individual sensation, motor and auditory alike? In the first place, the musical pace will be much retarded; secondly, those collective sensations consequent upon the fusing or grouping together of individual motor and auditory experiences will be broken up, so that the observance of rhythm in the more rapid passages will be difficult or impossible; and, thirdly, there will be uncertainty, characterized by the appearance of what has previously been referred to as the "question," *i.e.* the tendency to ask, "Is it this; or

is it that note," etc. Only when the automatic character of the memories has disappeared, only when the piece, in part or in whole, has been "forgotten," in the language of every day, is it advisable to relearn it by again invoking the method employed originally in its acquisition. It is worthy of note, however, that the forgetfulness is usually by no means as complete as might be inferred from the musician's inability to play. Soon—much sooner, in fact, than if the piece had never been committed to memory—automatism again asserts its sway; all of which goes to show that the impressions originally made upon the nervous system, though dulled, are by no means obliterated.

The Memory of the Singer.—In the previous discussion it has been abundantly shown that in those who play upon instruments the character of the memory is by dint of attention and repetition gradually transformed from a process essentially voluntary into one largely automatic. No such long and onerous exercises are demanded by the singer in order that he shall be put in the way of giving vocal expression to the musical ideas that he may have acquired or conceived. With him there is no need to establish the auditory-motor bond; it already exists, thanks to his possession of an exquisite and highly automatic instrument, which, unlike that of the musician whom we have before considered, is part of himself. Thus exempt, as it were, from the need of establishing new physiological relationships, he can give himself largely to the purely musical (auditory) side of memory the development of the voice itself following, under competent guidance, an essentially natural course.

With singers who are given to memorizing auditory association is the principal thing, though the words uttered possess, no doubt, ancillary importance, assisting, according to the testimony of lyric artists, in acquisition and reproduction alike. As for the recollection of the words, euphony, alliteration, and assonance play a considerable part, and this quite irrespective of the sense conveyed, though this, too, is an assistance.

The history of the gradual development of the voice in the child forms an exceedingly attractive chapter of psychology: how the vowels appear, then the consonants, and so to monosyllables, short phrases, and a larger coherency. So, too, with the musical use of the voice, which appears, however, much earlier in some children than in others.

Of still greater interest, were adequate data forthcoming, would be a description of the physiological mechanism underlying the wonderful *liaison* between the musical memory or idea and the motor mechanism immediately concerned in voice production. As information so explicit is not yet to be had, it will be well to abstain from theorizing.

Exceptional Manifestations of the Musical Memory.—It may be said without risk of contradiction that the majority of the great musical virtuosi disclose more or less remarkable powers of memory. But even among this class there are some who loom so large as to dwarf even the exceptionally endowed among their confrères. A typical example is that of the late Hans von Bülow, who, as the tradition goes, played "everything by heart." He could play for hours at a time without consulting his notes; knew all the works of Wagner "by heart," and thought it a hardship that the musicians of the orchestra were unable to play their individual parts in the same way. When a composer brought him a new score he would excuse himself and, passing into an adjoining apartment, take a hasty look at the manuscript. Returning thence in a few moments, he would seat himself at the piano, and, without a glance at the notes, play the entire composition to the great bewilderment, it may well be imagined, of the listening author.

Liszt, too, who is said to have played, among much else, most of the works of Beethoven from memory, is another instance of prodigious memory.

More extraordinary than the feats of musical memory of either Liszt or von Bülow are those told of Rubinstein, of whom it is said that, in a protracted series of concerts, he played upon the piano more than a thousand compositions, embracing about everything of value in the répertoire of that instrument.

The violinists, too, afford numerous examples of preternatural memory. The writer recalls an instance in point—a huge abdominal specimen, whose pulpy digits, moving with a kind of flabby waddle among the strings, seemed about as fit for playing as a jelly fish for dancing. And yet, as an offset to his physical disabilities, this man was dowered with an astonishing musical memory. Not only could he play "by ear" most of what he heard, but he could also recall nearly everything he had ever played. His répertoire was, indeed, enormous; technical shortcomings alone set a term to his acquisition.

Most of the great violinists—Kreutzer, Viotti, Rode, Corelli, Tortini, Baillot, Spohr, Paganini, De Bériot, Vieuxtemps, Sivori, Ernst, Kreisler, and many others—have given evidence on countless occasions of the posession of unusual powers of memory.

Nor have players on instruments other than the piano and violin failed to afford illustrations of remarkable musical memory. Here in New York may be heard one of the great flute virtuosi of the world, George Barrère, whose répertoire, already large, increases continually without manifest effort.

Opera singers have often been cited as examples of unusual musical memory; but, in the first place, as already pointed out, the association between the motor mechanism of the voice and the auditory representations is already established, and does not require the arduous labor expended by the instrumentalist in bringing about the association of the motor memories (of the fingers) with the auditory representations. Again, as already mentioned, the musical memory of the singer is greatly assisted by verbal associations derived from the libretto, no corresponding aid being found in the case of the instrumental virtuoso.

Most wonderful are the illustrations of musical memory afforded by certain conductors of the orchestra. One of these, Chevillard, conducted from memory nearly all the symphonies of Beethoven. The same thing had previously been done by Wagner. Here in New York we have been witnesses during the last few winters of a still more astounding performance. Sitting in the conductor's chair at the Metropolitan Opera may be seen Toscanini directing night after night almost every style of opera—Italian, French, German, and what not—without the aid of a single note. What is implied by an achievement of this sort can only be adequately appreciated by one who has studied the huge score of one of the modern lyric dramas. In concluding these brief remarks on musical hyperamnesia it is worth noting that the productive artists—the composers—do not always disclose the remarkable powers of memory possessed by the more gifted among

their reproductive colleagues. Of some it is said, that having composed them, they were obliged to commit their own works to memory, precisely as though they had come from a foreign pen. On the other hand, Mozart was able to write out the whole of the Miserere after hearing it at the Sistine Chapel twice.

Impairment, Loss, or Congenital Absence of the Musical Faculty, Amusia.—It was long ago pointed out by Falret that in those suffering from aphasia the musical faculty may or may not be lost. This statement has since been abundantly confirmed by numerous observers, notably by Grasset, Brown-Séquard, Gowers, and Knoblauch. From them we have the histories of certain aphasics who, incapable of uttering a single word, were able, none the less, to sing entire songs, rendering text and music from beginning to end without apparent difficulty. Scarcely less remarkable is the history of an aphasic musician recorded by Laségue. This individual, a sufferer from agraphia and alexia, could jot down melodies as they were sung to him quite naturally, as it seemed, and without effort. Equally extraordinary is the case of an aphasic lady observed by Proust, and quoted by von Frankl-Hochwart. This lady, whose musical gifts were of a high order, could write notes and even compose, and this despite the fact that although she recognized a melody when she heard it she was quite unable to sing it.

Neither space nor the objects of this paper admit of an elaborate discussion of aphasia, whose literature, already enormous, has of late taken on a controversial aspect. An introductory word or two recalling a few elementary facts which, it is hoped, will serve to make the present writing intelligible must suffice.

As all are aware, the general classification of aphasia involves the recognition of two varieties of the affection: (1) motor aphasia or aphasia of expression, and (2) sensory aphasia or aphasia of comprehension[6].

Under the head of motor aphasia we have aphemia, or the loss of the ability to utter words, and agraphia, loss of the ability to write them; and this despite the fact that the subject is able to comprehend what is said to him, to move his lips and tongue, and emit sounds.

Sensory aphasia, on the other hand, includes in the first place "word-blindness" or the inability to read what is either written or printed, vision and general intelligence remaining, meanwhile, unaffected, so that the subject is able to see the letters, but without being able to gather from them what they are intended to convey; and secondly "word-deafness," or the loss of ability to understand spoken words. The subject hears the voice, audition being unaffected, but the words fail to impart to him the meaning which under normal conditions they would convey.

According to present-day interpretation the centers for speech are situated in the left hemisphere for right-handed and in the right hemisphere for left-handed persons. Four speech centers are recognized: two of these are motor, two sensory in character. The motor expressional centers are concerned in the articulation of words and in writing; the sensory centers have to do with the comprehension of words spoken, written, or printed.

These centers lie along the Sylvian fissure; the motor center for the articulation of words (Broca) in the foot of the third (left) frontal convolution; that for writing in the foot of the second frontal convolution. The centers for the comprehension of spoken words, (left) and for printed or written words have already been indicated. Destruction of one or another or several of these centers gives rise to the various forms of aphasia, some of which are relatively simple, others exceedingly complex.

Now, under the head of sensory aphasia one finds included in many of the textbooks "amusia," by which is usually understood a form of psychical deafness characterized by the loss of the ability to recognize familiar melodies, or, in some instances, to discern the difference between harmony and dissonance. Amusia has likewise been made to include those cases in which all sense of time and rhythm is either lost or congenitally absent.

Not all writers on amusia, however, have been willing to use the word in this relatively restricted sense. Thus Wollaschek, writing as early as 1891, employs it in a far more generic manner than his predecessors, not excepting Knoblauch, himself responsible for the introduction into literature of the term "amusia." Wallaschek holds that amusia should be given a broad meaning, a meaning analogous to aphasia itself. Accordingly, he differentiates the following varieties: (1) motor amusia, in which the subject is able to comprehend music, but cannot sing; (2) sensory amusia or tone-deafness, (3) paramusia, in which, while he is able to sing, he uses wrong tones and intervals; (4) musical amusia, corresponding to verbal amusia (?) and finally (5) musical alexia and paralexia and musical amusia (instrumental), the latter characterized by inability to play an instrument. This classification, whatever else may be said of it, is scarcely justified by the clinical material now available.

Better far, because more simple and at the same time in closer accord with the facts observed, is the classification proposed by Dr. Brazier in 1892 (*Revue Philosophique*, Vol. XXXIV, pp. 337-368). Amusia, according to Brazier, may be simple or total or at any rate complex. Simple amusia may be subdivided into amusia of reception (centripetal amusia), and into amusia of transmission or expression (centrifugal) amusia. Under the head of centripetal or receptive amusia are included the auditory form or tone-deafness and the visual form or note-blindness (musical alexia); while under centrifugal or transmissive (expressive) amusia are included loss of the ability to sing, vocal (motor) amusia—or to play on instruments—instrumental (motor) amusia—the phenomenon being due to loss of the motor images relating to the exercise of the voice or to the playing of instruments.

Bearing in mind what has already been said regarding the importance of tone and motor recollection, sequential and simultaneous, and of the sense of rhythm and time, of harmony and dissonance, to the processes concerned in musical memory, whether acquisitive or reproductive, it is evident that defects involving one or more of these factors must result in impairment, greater or less, not only of musical recollection in particular, but likewise of the integrity of the musical faculty as a whole.

Amusia Associated with Aphasia.—The following synopsis of cases will serve to illustrate the association so frequently encountered of the various forms of aphasia with amusia in one or several of its phases. It must not be forgotten, however, that amusia may sometimes exist alone and unaccompanied by aphasia.

Aphasia and Agraphia with Musical Alexia and Musical Apraxia.—In the twenty-fourth volume of

the *Deutsche Zeitschrift für Nervenheilkunde* Dr. C. H. Würtzen gives with much detail the history of a case of this kind, of which the following is a synopsis: N. N., an unmarried woman, suffered an apoplectic attack in 1885, followed by aphasia, agraphia, and slight paralysis of the right arm and leg. These symptoms, save only the motor aphasia, which never entirely disappeared, were soon recovered from. Later, however, about a year and a half after the attack, she developed a psychosis and remained under treatment in an institution for nine years. Thereafter she lived with her sister, her mind lucid, her memory more especially being particularly good. When somewhat recovered from her apoplexy it was discovered that she had entirely lost her musical faculty. Still later, at a time when she was able to pronounce simple words only, she began to regain it. Sitting at the piano one day, it was quickly evident that while the tone and key (motor) memories of the left hand were intact, those of the right had entirely disappeared. Hence while the bass notes were correctly struck those higher up gave no sound, her right hand wandering in an uncertain questing kind of way over the treble end of the keyboard, but without touching it. Yet, despite this ineptitude of the right hand, her melodic memory is said to have remained unimpaired; for she could easily call up the recollection of both parts—the bass and the treble quite as well. When she made these attempts to play, it now and then appeared that the fingers of her right hand struck the keys, but always the wrong ones. While this state of things existed her right hand and arm had already regained much of their old-time vigor, and coordination was sufficiently good to enable her to write. Gradually she regained the ability to play with her right hand, and ultimately she was able to play by ear and memory in much the same way as before the attack. She was also able to compose minor music. The ability to play by note was, however, permanently lost.

This case is interesting for a variety of reasons, but more especially because it is a unique instance of what Würtzsen calls a malady of the "key-memory." As for the location of the lesion which is responsible for the occurrence of the phenomenon, he holds that we must look for it in the left hemisphere, more especially in Knoblauch's "Tone-movement image" center.

Aphemia, Word-Deafness, Word-Blindness, Agraphia, Reported by Von Frankel-Hochwart[7].—A man, 50 years old, had a cerebral hemorrhage, followed by hemiplegia of the right side, with loss of the power to speak or understand what was said to him, or to read or write. One day he began to sing a few bars from a melody, but without words. Since this first attempt he has frequently done the same thing, always singing the same fragment and always in the same way.

Aphemia, Partial Vocal (Motor) Amusia; Recognizes Melodies When They Are Sung, and Is Able to Repeat Them.[8]—Patient, a woman 55 years old. Attacks of vertigo, followed by partial paralysis of the right arm with loss of power to speak or understand what was said to her. Recovered somewhat from the paralysis and regained the ability to understand what was said to her. Was never able to read or write. Formerly was able to sing many melodies; at present can sing but part of a melody when the name of the song is mentioned. Can repeat a song when it is sung to her and recognizes popular melodies.

Word-Deafness, Tone-Deafness. — Bernhardt[9] gives the history of a man who was seized with vertigo, followed by right hemiparesis. A few days later he was restless and spoke very indistinctly. Still later, examination showed that he could write and read (aloud) and was able to hear tones and voices, but was unable to understand what was said to him. When he spoke he frequently mixed his words. Tests showed that he was unable to comprehend melody, which seemed to him like noise—now "high," now "low."

The foregoing illustrations are but a few of the many instances of the association of aphasia with amusia to be found in literature.

Amusia Without Aphasia.—Of especial significance to those who are interested in the study of disorders of the musical memory are those cases of amusia occurring independently, with slight, transitory or no aphasic complications whatever.

The following case of Würtzen's is an illustration in point. The subject, a man of 48, had acquired syphilis in his eighteenth year. Four months before coming under medical observation he suffered a stroke of apoplexy, with relatively slight loss of motion but complete hemianesthesia of the left side. Motion was largely regained in the left limbs and a slight thickness of speech soon disappeared. Despite this improvement, he was soon aware that he was unable to finger the strings of his violin properly and that he had entirely lost his sense of rhythm. A report of his condition, obtained from his family ten years later, showed that he had lost the power of tone-discrimination—could not tell whether a tone was false or true; could not sing; could not beat time, and had entirely lost his ability to play, being quite unable to find the proper notes with the left hand.

Peculiar interest attaches to this case by reason of the predominantly sensory character of the hemiplegic disturbance, the loss of motion from the beginning being insignificant.

In concluding his extremely interesting paper, Würtzen gives in much detail the histories of two cases of congenital amusia—"musical idiocy," as he calls it—the one observed in a student of medicine, the other in a single woman 32 years of age. Following are the principal phenomena observed. Inability to tell whether a piece of music is gay or sad; lack of the sense of melody; absence of the sense of time and rhythm and inability to dance; inability to discriminate between harmony and dissonance; no musical comprehension—the auditory impressions fail to evoke musical emotion, and are sensed as noise only; lack of the capacity to remember even the simplest melodies, or to sing or hum them; inability to recognize the difference in tone-color of the various instruments—flute, violin, piano, or what not. Such cases, though extreme and not very frequent, are nevertheless a broad hint of the conditions prevailing among the unmusical.

Brazier[10] gives the following histories of two cases of complex (mixed) or total amusia, occurring suddenly, the one in a singer, the other in a pianist: "In 1873, Barré, a tenor who was singing the important part of "Petite Fadette" at the Opéra-Comique, was suddenly seized one evening in the midst of the performance by total musical amusia. Neither the orchestra nor his associates, who sought to prompt him, succeeded in reviving his memory. He no longer understood what they were singing, nor could he emit a single note. On reaching home he was perfectly able to understand what was said to him in ordinary language and to reply intelligently, but

everything—words and music—which bore any relation whatever to the work which he had been singing, or, indeed, to any part of his entire repertoire,, was completely forgotten. He recovered in a few months and was able to resume his lyric activities."

Brazier's next case is that of the eminent pianist, Prudent, who, it seems, was endowed with a prodigious memory: "One day, about 1852, while playing in public with orchestral accompaniment one of his own concertos, he suddenly lost all memory of things musical. At that moment his work was for him nothing more than incoherent noise; not a phrase of the orchestra, not a melody did he comprehend. Coincidently there was absolute inability to play even from notes. He went abroad the following day, having largely recovered, but thenceforth played only with the notes before him."

In addition to the cases a synopsis of which has just been given, Brazier has placed on record several others, notably one of note-blindness (musical alexia) and one of tone-deafness, the first occurring in a music teacher, the second in a man 51 years of age.

Of the music teacher it is said that she had read music as easily as ordinary printing, and far more frequently, and that her musical education had been unusually thorough. One evening, after a prolonged attack of migraine, she seated herself at the piano and attempted, as was her habit, to play from memory. To her surprise, she experienced such a sense of uncertainty and the difficulties loomed so large that she felt compelled to have recourse to her notes. It was then that she made the discovery that she was utterly unable to read a measure or even a note, although she distinctly saw the characters. Despite this inability to comprehend musical notation she could read ordinary printing without apparent difficulty. Hardly less interesting is the fact that she heard and understood music, and could sing and play from memory perfectly. Three days after the attack she began to show signs of mending: she could comprehend the time values of the notes but not their pitch. Her recovery was complete on the fourth or fifth day.

Brazier's case of tone-deafness occurred, as has been said, in a man 51 years of age, who had suffered from repeated attacks of migraine, followed in some instances by aphasia lasting several hours. Subsequently he had an attack of migraine followed by tone-deafness, but without aphasic accompaniments. Music from a military band or piano was heard as noise only; so that, while he was able to refer it to its instrumental source, he was quite incapable of comprehending it as music. The affection was of brief duration, having completely disappeared in twenty-four hours.

Bernard[11] gives the history of a case of tone-deafness preceded by transitory aphemia and word-deafness. In this case autopsy revealed destruction of the middle and posterior portions of the (left) third frontal convolution, of the entire Island of Reil, of the first temporal convolution, of a small portion of the lower parietal lobe, and of portions of the basal ganglia as well.

Edgren[12] gives in much detail the history of a man of 34 who suffered from transitory paraphasia and word-deafness, and also from tone-deafness, the latter symptom persisting permanently. The incidence of these symptoms was due to traumatism of the head. Ultimately death ensued and an autopsy was had. This revealed destruction of the anterior two-thirds of the first temporal convolution, and of the anterior half of the second temporal convolution of the left hemisphere.

Chronic Meningitis (of Specific Origin) with Transitory Attacks of Aphasia—Musical Paralexia.—The writer has seen a case of this kind occurring in a musician of note, in whom one of the earliest phenomena observed was inability to read notes as they were written, this symptom appearing shortly *before* the occurrence of transitory attacks of aphasia, and persisting after the latter had entirely disappeared. In this instance specific treatment was of slight avail, the case advancing typically to dementia and death.

While, as clearly appears from the foregoing cases, amusia may exist without aphasia, and aphasia without amusia, the more frequent association of the two conditions is highly significant. So, too, is the apparent analogy existing between the various manifestations of amusia and the different forms of aphasia. In view of all this, and bearing in mind the paucity of decisive revelations from the dead house, what conception of the anatomical basis of amusia are we justified in entertaining? Edgren, who has carefully collected and analyzed all the material available at the time of publication of his excellent paper, holds that at least some forms of amusia may have an independent anatomical basis, and that this latter may be sought for in the neighborhood of these localities in which the various forms of aphasia are conventionally located. Respecting the anatomical seat of one form of amusia—tone-deafness—he is inclined to speak more definitely. To him the location of this form of the affection in the first or the first and second convolutions of the left temporal lobe, in front of the spot, injury to which gives rise to word-deafness, seems highly probable.

That children frequently sing before they talk; that idiots who are unable to talk sometimes sing; that drunken men often sing when they cannot talk, and that many birds sing, although they cannot be taught to speak, are some of the facts adduced in support of the contention that the cerebral (cortical) mechanism connected with musical representations is independent of that connected with those of speech. As an offset to this evidence, however, we are confronted by the fact, already sufficiently accentuated, that, while the musical faculty is sometimes preserved or largely preserved in aphasia, it is impaired or totally lost in a large number of well-authenticated cases.

How are these conflicting data to be reconciled? By what jugglery of inference are we to be put in the way of arriving at a theory which, even in moderate degree, shall comport with the exactions of common sense? Rather than invoke a factitious, though seductive semblance of solution, the writer confesses that in the present state of knowledge he is unable to frame an answer. Neither the pathological material nor the clinical histories associated with them are, in his opinion, either sufficiently abundant or of such a character as to afford the groundwork so necessary to a final solution of the problem. Nor is this to be wondered at when one considers the relatively small number of highly educated musicians, whose demise, conjoined with the favoring fortuities of complete clinical histories and carefully conducted autopsies, might, conceivably, yield the necessary data. In view of all this, it would seem idle to pursue the matter further; yet, because of their suggestiveness, the writer ventures, in concluding this nebulous phase of the subject, to cite certain outgivings of Brazier[13], which, though

published some years since, may still be read with profit. If we hold that the centers of musical representation and the centers of speech representation are identical, then we must admit, according to Brazier, that nervous elements which have become impotent for a certain order of representations (those of speech) remain active, nevertheless, insofar as certain others (those of music) are concerned. Or, if this hypothesis be rejected, there remains the alternative supposition that the cortical areas connected with musical representations lie near those concerned in speech.

Disorders of the Musical Memory Due to Hostile Emotions; Imperative Concepts (Psychasthenia) and Intoxication.

Besides the disorders of the musical memory due to gross lesions of circumscribed areas of the cortex, there are others, which, while obviously functional in origin, are capable of causing not only great distress to the subject, but even his complete artistic undoing. Several cases of this kind, some of them occurring in artists of the first rank, have come to the professional knowledge of the writer. The following are a few instances:

M. I. T., soprano of thirty-five, temperate, fine physique; never seriously ill, came to me with the following history: For several years—in fact, since the inception of her career as a church and concert singer—she had never been able to sing in public without the aid of copious stimulation, usually in the form of champagne, being so overcome with dread of a possible vocal mishap that her appearance in default of such assistance would, in her judgment, have been impossible. Wishing to put the matter to the proof, I prevailed upon her to attempt to sing for me without the accustomed prop, only a few other persons being present. When, however, it came to the test, she became greatly agitated and, declaring "that everything swam" before her eyes and that she "could remember nothing," sank down upon the sofa, trembling violently. A pint of champagne was given her, when presently, having gained her composure, she repeatedly sang with superb voice and in perfect style. It was the unanimous verdict of those who listened that her voice would have been an ornament to any stage. "Yes," she replied to this enthusiasm, "I have had many opportunities to sing in opera, but my infirmity, of which you have just been witness, has always stood in the way."

Later when the writer again saw her she was questioned as to her early life and education, with the hope of gaining a clue to the genesis of her trouble. Such a clue was not long in appearing. As a girl she had had, it seems, for some years as a vocal teacher an individual of violent and brutal temper, who, whenever she was guilty of a mistake, would strike her with a rod, heaping opprobrium upon her, at the same time, in the most abusive language. The effect of this ill-usage was to despoil her of both interest and confidence; to deprive her of self-possession, and, ultimately, to engender such dread of her own fallibility that she was otherwise powerless to cope with it save in the manner previously set forth. In her case stimulating medication, coupled with suggestion, was of sufficient avail to enable her after some time to sing without alcohol.

D. E. H., musician of forty-five, consulted the writer as to a peculiar disorder of the musical memory from which he had suffered for some time. As a violinist and member of a large orchestra his profession had taken him on frequent and extended tours throughout Canada and the United States. The fatigues and hardships of these journeys were great; and, to counteract exhaustion and depression, he began to take whisky, at first, at night, after the concert or rehearsal, ultimately several times during the day as well. He was rather tremulous when I saw him and complained of the usual digestive disturbances found in alcoholics, and of insomnia, as well. He was chiefly concerned, however, because of a symptom which had lately made its appearance—inability to play the notes as they were written. This infirmity had caused him much mortification. He had already been taken to task for his misplaying by the director of the orchestra, and he realized that his hold upon his position was precarious.

Such instances of musical paralexia are rather common. In a large percentage of cases the prognosis is favorable, the management differing but little from that of ordinary alcoholic cases. In this instance recovery was complete in about eight weeks.

S. K., opera singer, consulted the writer some years since with regard to an "unreasonable fear" of making her début in this country. This fear was the more surprising to her, as she had been singing for several years with success in some of the leading opera houses of Europe. As a child she had been moody and inclined to solitude; and, as she grew in years, she became a victim of various imperative concepts, developing, at the same time, a superstitious tendency entirely at variance with her rather rationalistic upbringing and the dictates of her own common sense. Appreciating, as she did, the essentially morbid character of these elements of her mental life, she was nevertheless powerless to overcome them; so that the appearance of her most recent dread, threatening, apparently, the ruin of her professional career, evoked a further and more poignant apprehension. When she sang, even at rehearsal, her heart beat violently, her memory wavered and despite the aid of the prompter she expected a break-down at any moment. The combined use of sedatives, stimulants, and suggestion proved sufficiently efficacious to enable her on the night of her début to get through the first act, and the succeeding liberal applause helped her through the rest. Cases resembling this one in their emotional phases are not unknown to the theater; but the antecedent neurotic features are fortunately rarer.

In bringing together the material embodied in this paper, the writer hazards the hope that he has not been engaged in a bootless task; and he is encouraged in this, not only by appreciation of the clinical interest attaching to it, but still more because of the ever-increasing rôle of that art which can "make passionate the sense of hearing" in the life of the modern world.

THE SURGICAL TREATMENT OF GOITER.*

By W. D. HAMILTON, M.D.,

COLUMBUS, O.

The popular conception of a medical term is sometimes of interest. The Century Dictionary defines *goiter* as "a morbid enlargement of the thyroid gland on the front part and side, or sides, of the neck." However, to be somewhat more specific, a parenchymatous goiter,—that type of the disease often observable in many young misses just entering womanhood,—is one in which the whole thyroid gland is enlarged, all its vesicles being distended with colloid secretion.

While, to avoid error, careful examination of the gland should be made in every case of goiter, those of the small parenchymatous type, not causing dyspnea, are as a rule medical cases, and will very often get well under good hygienic surroundings, even if nothing in the way of drugs be employed, though the preparations of iodine often seem to be of benefit to them.

It is, however, surprising how often in our surgical work we meet with cases in which the enlargement of the thyroid gland is found to be due apparently to a circumscribed nodule, cyst, or neoplasm in its substance. It may either be in one lobe or in the isthmus of the gland, and it may have reached in its lower encroachments below the sterno-clavicular line, and it is in the latter class that the more formidable pressure effects are observed.

The importance of giving these growths attention would not be questioned were they to occur in the female breast, where they so often terminate in malignant disease. Cancer of the thyroid gland occasionally occurs, and in the sixty-five cases that form the subject of this discussion our pathologist found it to be present in two instances, while in a third case there was much to suggest the possibility of carcinomatous change.

On account of the pressure effects upon the trachea and the vessels of the neck, and the subsequent pathological influence which a goiter may produce upon the heart and lungs, it is important to anticipate these changes by recognizing neoplasms in the substance of the gland as soon as it is practicable to do so. The writer has been impressed with the frequency of their occurrence.

An apparently prevalent medical notion on this subject is that iodine used in some way or other is generally a useful therapeutic agent in the treatment of goiter, without reference to the type of disease represented. Before the drug is employed, however, it is well to bear in mind the fact that if one be dealing with a growth in the substance of the gland, the iodine may not only be of no avail, but if it has been used by injection, aside from the immediate risk of sepsis, hemorrhage, hematocele, thrombosis, or embolism from its use, it may give rise to dense and leathery adhesions on account of which the subsequent removal of the goiter by operation will be made a very much more serious and difficult affair than if the drug has not been employed.

In the treatment of Graves' disease it is of importance that there should be a resort to surgery as soon as there is strong presumptive evidence that the disease is imminent or actually present. The operation usually contemplates the removal eventually of a part of the thyroid gland. As a preliminary measure, however, the blood-vessels of supply to the gland may require ligation, so that after the lapse of an interval, when the patient may have acquired more strength, the removal of a portion of the gland may with more safety be done. Some of these sufferers from Basedow's or Graves' disease are very much enfeebled, reduced in both flesh and strength. A great many of them, after simple ligation of the vessels of supply, increase in weight in an amount varying from a few pounds to 40 or 50 pounds within a few months.

The writer is satisfied that many medical men are skeptical about the efficiency of operation for the relief of Graves' disease. This is probably due to inexperience with its results. No doubt the notion prevails among many that operation is largely speculative and that the results are doubtful or fanciful. In the opinion of the writer, where either a fatal outcome or doubtful benefits arise from operation for Graves' disease, the general pathological damage has become so marked that even surgical interference may no longer offer its full benefits. We see the analogue of that in various surgical conditions; hopeless carcinoma of the stomach following ulcer; advanced biliary sepsis from stones in the common duct of the liver, and numerous formidable complications which become the precursors of death, following any case of gall-stones which may have originated in the gall-bladder. These late conditions in no way argue the inefficiency of surgery, but rather emphasize the importance of early operation before these unfortunate sequelæ arise. In cases of Graves' disease and in goiters of all sorts operated upon during the period in which surgery is applicable, we have had an abundance of evidence in the individuals restored to comparative health, so that the writer feels that his contention is a perfectly justifiable one as to the efficiency of surgery in all of these cases that form the subject of this discussion.

We should cultivate the habit of examination of the neck in any and all cases in which the thyroid gland is enlarged, if hitherto it has not been a routine undertaking in our diagnostic efforts. Many of the cases operated upon by us were not especially apparent to casual observation, and many of them would certainly have escaped detection if they had not been studied with care and discernment. Physical examination of the neck should include the palpation and inspection of the thyroid gland to enable one to detect, if present, any pathological peculiarity. When the thyroid gland is enlarged it should be carefully examined, the kinds of change from the normal which it has undergone, and the history thereof being noted. Pressure effects upon the trachea may in some measure be anticipated by the early recognition and removal of neoplasms from the substance of the thyroid gland, and there is usually some deleterious effect in the way of compression even though the growth be of very moderate proportions.

In this connection the question will arise as to

*Delivered before the Columbus Academy of Medicine, October 16, 1911.

whether the enlargement of the gland is diffuse or circumscribed, fluctuant or solid, fixed or movable, nodular or homogeneous; if there is associated with it a condition of larger blood-vessels than the normal; whether it is growing or not; and perhaps of greater importance still, whether the pressure of the goiter on the windpipe is such as to impede or to embarrass respiration; whether the pressure is from the growth all in the neck or partly buried in the upper part of the chest, and whether the blood-vessels of the neck, and secondarily those of the heart and lungs, are undergoing degenerative changes resulting therefrom.

Or can it be that this patient who has of late been mercurial, feeble, excitable, with rather a rapid pulse and no decided fever, can it be that she who has only a moderate enlargement of the thyroid gland is developing exophthalmic goiter? If so, the administration thrice daily, for two days—not longer—of five-grain tablets of thyroid extract of the sheep will, in all probability, cause the pulse to increase in frequency, and the toxemia to become more profound, and such a reaction may have diagnostic value; or the failure of the drug to affect the pulse may be quite as instructive as showing the probable absence of Basedow's or Graves' disease.

Early operation will minimize the risk and will offer a better chance of cure is most goiters, excepting those of the small parenchymatous variety, not causing dyspnea, which, as above stated, are not surgical cases. In examining the neck it is always well to see whether there is atrophy of the thyroid gland, which is quite liable to be found in cases of myxedema.

Most tumors met with in the surgery of the thyroid gland are benign in character. The location of the growth with reference to the thoracic inlet or to the windpipe will determine the amount of dyspnea, if there is any in a given instance. A benign neoplasm in this location may ultimately and sometimes unexpectedly, cause a fatal attack of suffocation. As in other parts of the body, an innocent growth may here develop the characteristics of malignancy, and furthermore, emphysema, bronchitis, thrombosis, cardiac weakness, or paralysis of the inferior laryngeal nerves may be the result of pressure from a goiter.

The important relation of the thyroid gland to the central nervous system and to the nutritive processes is shown in cases of exophthalmic goiter and in those of myxedema as well. While there is a more or less complete set of symptoms in the former, and while an associated well-marked bruit over the superior thyroid arteries is pathognomic of exophthalmic goiter, there are no doubt stages in its early development in which the bruit is absent, where hyperthyroidism is present, and where the patient's rapid pulse and other associated symptoms tend to show that the disease is either imminent or in process of development. I am convinced that exophthalmic goiter is not so uncommon as some general practitioners assume. Tachycardia and enlargement of the thyroid gland are its usual accompaniments. With reference to the significance of tachycardia, a physical examination of the lungs is of the utmost importance to exclude pulmonary tuberculosis, for occasionally it may be necessary to differentiate between it and Graves' disease. When in doubt as to the diagnosis in cases which have seemed obscure, where there is a rapid heart action, with or without febrile movement, and in which there is nothing in the nervous, pulmonary or cardiac apparatus *per se* to explain the frequent pulse, one should think of the possibility of Graves' disease. The bulging of the eyeballs may not develop early. Trembling of the hands, fatigue in the legs in locomotion, impaired ability to climb the stairs or to make ordinary physical or mental effort, oppression about the heart, anemia, emotionalism, nausea or vomiting, diarrhea, sweating, and emaciation may be more or less evident.

If the phonendoscope is applied to either of the superior thyroid arteries in pronounced cases, a distinct bruit can often be elicited. The disease may be of but a few months' duration, and yet may be quite complete in its symptomatology. On the other hand, it may have existed for years. Periods of recession with apparent improvement or subsidence may at times occur even though medication for its relief has not been employed.

Particularly in adults the following types of goiter should be treated with early operation: all nodular, cystic, and adherent tumors in the substance of the thyroid gland; malignant disease if sufficiently circumscribed, and cases of exophthalmic goiter. The insidious, increasing pressure on the windpipe produced by a growing goiter should be taken into account with reference to the operative needs of the case, for in addition to the deformity so frequently produced by the disease, it may extend for some distance downward into the thorax. Sometimes arteries of supply to the gland are tied as a preliminary operation, especially in exophthalmic goiter. This may modify the conditions so that a successful thyroidectomy may be done on a subsequent occasion.

Kocher has been the most forceful pioneer in this work. He has had in his clinic up to a recent date 3333 thyroidectomies, with only four deaths in his last thousand, and it is an interesting fact in this connection that the fatalities were all of them in individuals who, as the result of undue procrastination, had become wretched subjects for operation. The inferences from his work are of the greatest value to the profession. Large incisions, deliberate painstaking hemostasis, and the avoidance of antiseptics in the wound characterize his work. He has done a great many of these operations of all sorts under local anesthesia. Relying upon his views and experiences, we have done much of our recent goiter work in the same way. It is a great satisfaction to have the patient conscious and able to talk during the operation. The occurrence of injury to the recurrent laryngeal nerve or nerves, of nausea and vomiting, of pneumonia, or of postoperative hemorrhage is thus minimized. And, too, the straining often attending vomiting after general anesthesia may cause oozing of blood or an hematocele and suppuration following it. In the service of Dr. Charles Hamilton and myself there have been no deaths following our last sixty-five operations of all sorts upon the thyroid gland.

There is no reliable medical specific for either ordinary or exophthalmic goiter. The variety of medical treatment at various times employed is about the best possible evidence of its unreliability in the treatment of Graves' disease. Operation comes nearer being a specific, so to speak, than anything heretofore offered with which the writer is familiar. Early operation will generally cure such cases of goiter as are suitable for surgical interference, and a fair majority at least of cases of Graves' disease

It is not expected that these arguments will convince everybody. There always will be, as at the present time there are, medical men who persist in treating cases of appendicitis and other perilous surgical lesions. Among this number, however, will be found the majority of those internists who unfortunately do not get the patient to surgery until perhaps hopeless damage has been done. Fortunately, most medical men do not belong in this category.

150 East Broad Street.

TOXEMIAS OF PREGNANCY.

By S. H. BLODGETT, M.D.,

Boston, Mass.

At the beginning of this paper I shall have to offer a word of apology or explanation because in speaking of the toxemias of pregnancy I shall limit myself to those toxemias only of which some of the symptoms can be discovered by means of an examination of the urine. These, so far as we know at present, consist of only two; first, the commonly so-called uremic toxemia, and, second, that one (to which so far no name has been given) which causes an incorrect action of the pancreas and which is marked by vomiting and by the appearance of acetone and diacetic acid in the urine.

Of course it is a well known fact that it is not the retention of urea in the system that causes the clinical symptoms which we call uremic poisoning, but just what the exact poison is has not as yet been determined, so that at the present time, at least, we have to depend for our knowledge of the presence of this form of toxemia, and our premonition of the probable occurrence of convulsions, on the amount of urea excreted by the kidney as shown by the urinary analysis; taking into consideration, before giving our final judgment, the amount of nitrogenous food taken into the system and the amount of physical or muscular exercise indulged in at the time that the urine was being collected. It is sometimes claimed that without knowing the exact amount of nitrogenous food taken into the system we cannot tell what the exact elimination of urea in the urine ought to be. Theoretically, this may to a certain extent be true, but from the practical and clinical standpoint (and I speak as one who sees the periodical analyses of the urine of four or five hundred cases of pregnancy each year, and as one who is also fortunate enough to see the clinical outcome of these same cases), I can say that by considering the amount of urea eliminated in the urine in connection with the other things which I have mentioned, and considering the relation of the urea to the other solids, and the amount of albumin in the urine, we can very accurately foretell whether there is liability of the occurrence of uremic convulsions.

There are two forms of poisoning due to the uremic toxin; one develops very slowly and the poisoning goes on for some time more or less progressively. This form may occur at any time during pregnancy after the third month, but most frequently during the seventh or eighth month. The other form develops much more rapidly and usually occurs during the ninth month. In the first form the patient will give in answer to inquiries a history of having for some time had headaches at intervals, of partial loss of appetite, of lassitude, and of digestive disturbance, not, however, as a rule to the extent of vomiting; perhaps even of attacks of blindness and pains along the course of the nerves. The examination of the urine will show an excretion of solids from 30 to 60 grams, an excretion of urea from 5 to 10 grams, and from a slight trace to a considerable amount of albumin, with possibly a few casts; while the patient is taking an ordinary nitrogenous, varied diet. As this condition progresses we shall find that, while the nitrogenous food taken in is not decreased, the urea eliminated slowly but steadily decreases. This I consider one of the most important symptoms and believe that when the daily excretion of urea has fallen below 9 or 10 grams per day, while the patient is taking the average amount of nitrogenous food, we ought to watch the case very carefully.

The treatment will vary according to the symptoms and the results of the uranalysis present when we discover the condition. If we find that the urea is decreasing rather slowly, while the nitrogenous food taken by the patient has not been decreased in amount, we should limit very decidedly the amount of nitrogenous food, especially animal fiber, which the patient is allowed to take, and watch under these conditions the daily excretion of urea. A milk diet, when the condition is recognized early enough, is not necessary; but a large amount of liquid should be taken in the form of water, milk, and hot drinks. The amount of exercise which the person takes should be somewhat limited, also. If the treatment is going to have a beneficial effect, the amount of urea excreted will probably begin slightly to increase, and after it has become normal the patient can gradually be put back onto the ordinary diet, but the urea output should be watched carefully during the rest of pregnancy.

I would here call attention to the fact that the urea output in pregnancy is less than when in the non-pregnant condition and my experience is that a urea output of 15 grams in a pregnant woman would correspond with a urea output of about 20 grams in the same woman on the same diet when not pregnant. If, however, we have not discovered the deficient elimination of urea until it has progressed somewhat further, or if our early treatment does not produce the desired result, the nitrogenous elements of the diet should be still farther reduced, and the patient can have only fruits such as oranges, grape fruit, etc., and a milk diet, with what bread or crackers she may like.

I have discovered that as a matter of practice in giving a milk diet it is usually better relished by the patient and can be borne for a longer time without upsetting the digestion and causing a coated tongue if the patient is given a milk low in fat content. This can be accomplished by getting a partially skimmed milk or a milk which has set for twelve hours and from which the upper third has been poured off. As a matter of experience I have found that Holstein milk, when the patient has to be kept on a milk diet for a length of time, agrees better with the average patient and is more palatable than the Jersey or Guernsey milk.

The amount of physical exercise allowed should be reduced to a minimum, and if the urine does not amount to at least 1200 c.c. in twenty-four hours the patient should be advised to drink at stated times in the day at least eight ounces of water as hot as possible, and plenty of water at any time. In this form of toxemia the first serious effect of the poison is on the fetus; the fetal heart beat should be watched very carefully, and if this begins to weaken or ceases labor should be induced at once.

Care should be used to keep the skin in good condition and fairly active by the use of sufficient clothing and daily friction, but much bathing, unless under the greatest precautions against allowing a chilling of the body, should not be advised. If this treatment does not cause improvement or if we have not discovered the condition of the patient until it has apparently been progressing for some time, as instanced by a very low urea output and some of the clinical symptoms of so-called uremic toxemia, the question which confronts us is the termination of pregnancy. Here I wish to enter a very earnest plea against putting off too long the induction of labor, but I also wish to register my protest against the induction of labor indiscriminately in all cases in which the urea output may happen to be abnormally low. Before deciding finally in regard to the induction of labor, the urine analysis, the viability of the child, the clinical symptoms, and the prospect of improvement from treatment should all be carefully considered. We should remember that in this form of toxemia the child usually shows the first serious effect of the poison and we should carefully watch the fetal heart beat and if it begins to weaken or ceases altogether we should induce labor without delay.

The statistics presented below will have a great bearing on this particular point. If, after going over our case carefully and taking everything into consideration, it seems probable that convulsions are likely to occur I must very strongly urge the induction of labor at once, as in this case we can be sure of saving the mother's life and if the child is viable the child's life also; whereas, if we wait until convulsions occur the child is almost certain to be born dead or to die a few hours after birth, and we have very much less chance of saving the mother's life, while even if it is saved she will have serious kidney trouble following, for it has been my experience that the kidney condition which follows convulsions from this cause is far more serious and more lasting than when the poisoning of the mother has not progressed far enough to cause convulsions. In these cases also it is very important that the patient should not take any physical exercise. I have frequently seen cases in which the patient was showing symptoms and the urinary analysis indicated possible convulsions in which an attack of eclampsia was induced by a walk of a mile or two or by some other slight physical exercise, so that when it is decided to induce labor it is often necessary in urgent cases to etherize and remove the fetus as rapidly as possible, not allowing the woman to make any physical exertion at all.

Following the induction of labor we should give the patient a large amount of liquid so as to have a large amount of urine passed. Almost always nature tries to accomplish this herself and I have seen 14 quarts of urine passed in the 24 hours following the induction of labor when convulsions were imminent. If, however, we have not seen the case until convulsions have already occurred, we should empty the uterus as rapidly as possible, in order to prevent any more muscular exertion and consequent breaking down of muscular tissue, and if the convulsions continue after labor we should place the patient in hot packs and induce free perspiration and free movement of the bowels, even in some cases removing a pint of blood from the arm and replacing it with a pint of saline solution. But one should not in these cases use chloroform or ether to control the convulsions, as the kidney is already seriously damaged and ether or chloroform will add to the disturbance.

A rather odd thing that I have noticed in these cases has been that, when the patient has been taking an average amount of nitrogenous food daily and the urea output has been decreasing, if we stop the nitrogenous food entirely for several days, the urea output will increase very markedly, and the patient will feel better than she has for some time.

The second form of toxemia, attended by a low urea output, comes on very rapidly, sometimes even within a day or two. In these cases the symptoms are much more sudden in their onset, the history often being that the patient had apparently been perfectly well up to the occurrence of the convulsions, but in the majority of cases one will find on careful inquiry that for a few days she had had rather sudden severe headaches, pains along the course of some of the nerves, and pain in the stomach, with coated tongue and loss of appetite. The urine is small in amount as a rule, the specific gravity rather high, and the amount of urea low, sometimes as low as 4 or 6 grams in twenty-four hours. In such cases convulsions are imminent, and emptying of the uterus should take place at once, attended by the least possible physical exertion for the patient. If convulsions do occur in these cases they are likely to be more severe than in the class previously described and the prognosis is more serious so far as the mother is concerned but much better for the child, because the poisoning comes on so rapidly that there has not been time for the child to be seriously affected. It is in the fatal cases following this form of toxemia that on post-mortem examination we find marked changes in the liver. In this form, if an anesthetic is necessary, one should be sure to use ether, but after convulsions have occurred one should not use any anesthetic unless absolutely necessary. If any must be used, one should employ ether and oxygen.

If convulsions have occurred in a case of this class we should use the same treatment recommended in the previous form, emptying the uterus, and, if the convulsions do not cease, we should use hot packs to cause perspiration, obtain free evacuation of the bowels, and bleed, but should not force the ingestion of liquids.

As for the other toxemia about which I shall speak, while it is not strictly limited to pregnancy, still as about 90 per cent. of the cases occur during pregnancy it seems to me that it should be mentioned here. Of this I shall speak very briefly. This toxin affects primarily the pancreas and the clinical symptoms are nausea and vomiting; the means by which we determine that the nausea and vomiting are due to this particular toxemia is by the discovery of acetone and diacetic acid in the urine. In every one of these cases one will find on deep pressure over the head of the pancreas a decided sore spot, and in some cases even without any pressure the patient will complain of a pain deeply seated in the pancreatic region. The nausea and vomiting may vary in degree from vomiting during part of the day only to pernicious vomiting, where everything that is taken into the stomach is rejected, and where even without having taken food the patient vomits mucous fluid every few minutes day and night. If in a case of vomiting we find acetone and diacetic acid in the urine we may be sure that this form of toxemia is present, and that the administration of bicarbonate of sodium and proper regulation of food will relieve the condi-

tion. Of course one can easily understand that it may be exceedingly difficult, in the case of a patient who is vomiting constantly, to introduce into the system and have retained enough bicarbonate of sodium to take effect, and it is this problem that constitutes the only difficulty in the treatment. Bicarbonate of sodium given in a rectal enema is absolutely valueless, but it can almost always be given by the mouth, and if for any reason that should be impossible it can be given under the skin or even intravenously. I have never had to give more than 60 grains a day, and usually not over 20. In some cases the result will be immediate and in others we have to persist with the medicine for two or three days before we begin to see much diminution in the vomiting. It may be of interest if I mention a few ways in which the bicarbonate of sodium can be given. In some cases we have to use one of these methods; in other cases another. It can be prescribed: five grains dissolved in half a glass of water, repeated three or four times a day; or twenty grains dissolved in a glass of water, sipped frequently enough so that the whole amount is taken in twenty-four hours; or, to make it palatable to the patient, two and a half grains can be put in half a cup of hot water to which just enough weak tea (or a few drops of lemon juice, if tea is disliked) has been added to color it; this to be repeated every three to five hours. As I have said before, the principal point in this treatment is the ingenuity often required to get the bicarbonate of sodium into the patient. In some cases the improvement will be immediate, but in some severe cases, on account of the persistent vomiting or where the toxemia has been active for some time, it may be several days before improvement is seen.

In relation to the diet, as I have said before, I allow the patient to eat anything she may have a fancy for, but in exceedingly small amounts, and one must be very careful not to increase the amount of food quite as rapidly as the patient's appetite indicates. I have tried several series of cases with different classes of food for diet and have found that the best results were obtained when patients were allowed to have any articles of food for which they had a preference, but in very minute quantities, such as 1 oz. of milk and a piece of uneeda biscuit about one-half inch square repeated every two hours, or any other food that the patient craves, remembering to give it in these minute quantities.

As the acetone and diacetic acid disappear from the urine (which may not be for several days after the vomiting has begun to improve) I begin to decrease the daily amount of bicarbonate of sodium until we get down to five grains a day, which is continued sometimes until the patient is up and about again, and feeling as well as ever. In this connection I would note that there are other forms of vomiting besides those in which this toxin is present, and these other cases are not benefited by the bicarbonate of sodium treatment. Therefore, before beginning the treatment of a case of vomiting of pregnancy by bicarbonate of sodium, one should find out by means of the simple tests which any physician can make in his office whether the vomiting is caused by this particular toxin. As a matter of practice, I have noticed that the vomiting due to this toxin is more persistent and takes a few days longer to control in the earlier part of pregnancy than during the later stages.

I will add here the common clinical tests for acetone and diacetic acid. For acetone: Take a small amount of urine, say 2 drams, to this add 15 or 20 drops of acetic acid, then add a few drops of an aqueous solution of sodium nitroprussiate; in adding this latter one must be careful not to add enough to change decidedly the color of the specimen being tested; then add a dram or two of ammonia. If acetone is present, the color will slowly change to an amythest and then to a very deep red, depending upon the amount of acetone present.

The clinical test for diacetic acid, while it is not an absolutely reliable one, is a very simple one, and for that reason is the best clinical test which we have. It is best done in a test-tube, but even this is not necessary. To a small amount (about an ounce) of urine add, drop by drop, a solution in water of terchloride of iron. As the drops of solution of terchloride of iron fall through the urine they will become red and then change to white, if diacetic acid is present. If for any reason there is a question whether the drops change to red or not, if we filter the urine, to which has been added the iron solution, and then to the filtrate add more of the iron solution, we shall be enabled to see the red color more distinctly.

As a sort of postscript and to point the moral to some of the statements which I have made regarding the induction of labor where convulsions are threatened, I will present in tabular form the statistics of the Maternity Department of the Massachusetts Homeopathic Hospital for the past two years:

1909

518 confinements, 4 emergency convulsions, 10 induced cases

	Urinary Symptoms	Induced	LIVED		DIED	
			Mother	Child	Mother	Child
5	low urea + considerable albumin	late	0	0	5	5
2	low urea + considerable albumin + symptoms	late	0	0	2	2
1	low urea + considerable albumin + symptoms	early	1	1	0	0
1	low urea + trace albumin	early	1	1	0	0
1	low urea + trace albumin	early	1	0	0	1
10			3	2	7	8

1910

568 confinements, 4 emergency convulsions, 13 induced cases

	Urinary Symptoms	Induced	LIVED		DIED	
			Mother	Child	Mother	Child
1	low urea + considerable albumin	early	0	0	1	1
2	low urea + considerable albumin	early	2	0	0	2
4	low urea + considerable albumin	early	4	4	0	0
2	low urea + considerable albumin	early	2	0	0	-
2	low urea + trace albumin	early	2	0	0	2
1	normal urea + considerable albumin + symptoms	early	1	0	0	1
1	normal urea + slight trace + symptoms	early	1	0	0	1
13			12	4	1	6

*Children not viable.
†Child died by accident

In 1909 there were 518 cases of labor occurring at the hospital. Included in these were 4 emergency cases, that is, 4 cases that were in convulsions when admitted to the hospital; 10 cases of convulsions which occurred after the patient had been admitted to the hospital, and I have classified them as induced cases because labor was induced either before or after convulsions commenced. To

explain the terms "early" and "late," as applied to the induction of labor, I mean as far as these 1909 statistics go that a late induction denotes labor was induced the moment a positive symptom of a convulsive nature began, and by early induction I mean that labor was induced when we felt positive that it could be, at most, only a few hours before convulsions would occur.

In studying these cases from the urinary standpoint, we find there were five where the urine showed a low urea and a large amount of albumin. Here labor was induced as soon as the first indications of convulsions were apparent. In these five cases the five mothers died and the five children died. There were two cases with a low urea output, a large amount of albumin, and the so-called uremic symptoms (these two cases had headache, attacks of blindness, etc.). Labor was induced after convulsions began and both women died. There was one case which showed a low urea, a large amount of albumin, and uremic symptoms, in which labor was induced early. We thought convulsions were coming on directly, and labor was induced before convulsions had occurred and the mother and child both lived. There was one case of low urea and a trace of albumin. Labor was induced early and both lived. There was one other case where the urine showed a low urea and a trace of albumin. Labor was induced early and the mother lived but the child died. Out of these ten cases seven mothers died and eight children.

In 1910 we thought we would try the induction of labor earlier, when we thought convulsions were liable to occur, instead of waiting. There were 568 confinements during this year, the same number of cases of emergency convulsions were brought to the hospital, and in addition there were thirteen cases that we classified as induced cases.

In analyzing these we find that there were nine cases in which there were low urea and a large amount of albumin. In one case both the mother and child died; in two cases the mothers lived, but the children died; and in four cases both the mothers and the children lived. There were two cases in which labor was induced so early in each that the child was not viable, but both mothers lived, however. There were two cases of low urea with a trace of albumin in which labor was induced early and the mothers lived, also the children. There was one case in which the urea was normal, accompanied by a large amount of albumin and uremic symptoms. Labor was induced early, the mother lived, but the child died from an accident. I have forgotten what the accident was, but I think it was the cord around the neck. Anyway, it had nothing to do with the poisoning. There was one case of normal urea with a slight trace of albumin and uremic symptoms. One of the symptoms in this case especially was the weakening of the fetal heart. The mother lived and the child died three hours after it was born.

The numbers are so large that I think it is perfectly fair to compare the results. Seven mothers died in 1909 and only one died in 1910. Eight children died in 1909 and only six died in 1910. I have not counted the child that died from the accident, but I have counted the child that died when labor was not induced until the fetal heart began to show the effects of the poisoning. If we had induced labor in this case some hours earlier and not waited until the fetal heart began to fail, we could, I feel confident, have saved the child.

These statistics show that during 1909 in 518 confinements there were ten cases where convulsions occurred. In these convulsion cases 70 per cent. of the mothers died and 80 per cent. of the children; while in 1910 in 568 confinements there were thirteen cases in which we felt certain convulsions would occur and labor was induced (not in some of the cases, however, as early as I should now advise it). In these thirteen cases 11 per cent. of the mothers and 46 per cent. of the children died.

419 Boylston Street.

OMPHALORRHAGIA NEONATORUM.

By JOHN H. RICHARDS, M.D.,

NEW YORK,

LECTURER GYNECOLOGY, NEW YORK POLYCLINIC; INSTRUCTOR CLINICAL PATHOLOGY, CORNELL MEDICAL COLLEGE.

Various authors have described bleeding from the freshly discharged umbilical stump as hemophilia of the newborn, secondary hemorrhage from the umbilical stump with sepsis, hemorrhagic manifestations of syphilis, and other diseases in the newborn, etc. The majority of writers on the subject, however, believe that there is no relation between syphilis, sepsis, or hemophilia and this condition. Grandidier[1] reported 576 bleeders, of which only twelve showed any hemorrhage from any place during the first few days after birth. He states that only rarely do symptoms of hemophilia develop before the end of the first year. J. W. Legg[2] says that this condition is separated from hemophilia by the fact that after the bleeding from the cord has stopped there is no further tendency to bleed during life, and hemophilia is incurably chronic. Edgar[3] separates it from hemophilia, and calls the condition omphalorrhagia. This term describes the condition without attempting the etiology, and in view of the obscurity of the etiology I think that it is a good term. I will return to a discussion of the etiology later. I mention its relation to hemophilia simply that I might make it clear that there is no further relation than that they are both diseases in which is found defective coagulation of the blood. They differ in every essential respect, and the disease in question should not be called hemophilia.

As to the frequency of the condition Townsend[4] has given the following statistics: Of 5,225 births at the Boston Lying-in Asylum there were only 32 cases of all classes of hemorrhage. In the Lying-in Asylum of Prague Ritter[5] found as high as 1.4 per cent. The histories of the cases as a whole present nothing characteristic. The children are not especially feeble, nor are they born of feeble parents. They present no peculiarities of any character whatever excepting the bleeding.

History of Baby L.—Family history: Father 38 years old, strong and well. No history of syphilis or other chronic disease. Wassermann reaction negative. No member of family has hemophilia. Coagulation time normal. Mother 36 years old, strong and well. No history of syphilis or other chronic disease. Wassermann reaction negative. Two uncles and grandfather on mother's side give history of hemophilia. In the retrospect the mother thinks that she bleeds more than do most people. I have repeatedly taken her coagulation time, and it is uniformly increased, varying between 11 and 15 minutes, excepting on the sixth day post partum, when the coagulation time was 16 minutes. After eight years of married life with a normal sexual

history the mother for the first time missed her menses of October 8, 1908. She had a normal pregnancy. On account of her age, and following the advice of W. Gill Wylie,[8] I induced labor ten days before the expected time. This was followed by a normal single birth, with nothing of interest during the labor. The child was a well-developed child of eight pounds. On the fifth day the cord dropped off and the stump was clean. There was no jaundice present. On the night of the day on which the cord dropped off I was hurriedly called by the nurse on account of profuse bleeding from the umbilicus. On my arrival the bleeding had reached alarming proportions. The child appeared exsanguinated, and was gasping for breath. I could not feel the pulse at the wrist. The heart beat was very fast and weak. The child appeared lifeless. As fast as possible I tried to stop the bleeding, first by compression, and then by ligature. I sent for Dr. Bolling Lee in consultation. He, finding that there was bleeding between the sutures that I had placed, put a purse string suture around the umbilicus and lifted the stump up by forceps and then tied the suture. This stopped the bleeding. Then I noticed that there was bleeding from the nose and gums. Also, there was blood passed from the bowel and a little was vomited. At the suggestion of Thomas W. Hastings,[7] serum obtained from the father's blood was given. This was given in doses of 30 minims each hypodermically every three hours. Soon after the administration of the first dose the blood began to clot. This was the first clotting seen. We continued the serum for a period of four days. The coagulation time of the baby's blood was as follows: On the sixth day following the beginning of the hemorrhage there was no tendency for the blood to clot whatever. Drying took place before clotting. On the same day after the serum had been given the time was 40 minutes. On the seventh day the time was but 15 minutes. From this time on there was a gradual shortening of the coagulation time to within normal limits, where it has remained up to date. On several occasions the baby has had slight scratches, but there has been no tendency to abnormal bleeding. The general blood examinations were as follows:

Day.	6th.	8th.	10th	14th	60th
Hemoglobin	18 per cent.	25 per cent.	31 per cent.	38 per cent.	58 per cent.
Red cells	2,112,000	3,000,000	3,448,000	3,520,000	4,168,000
Index	.4	.4	.45	.54	.71
White cells	41,000	42,000	38,000	30,000	12,000
Blasts	xxx	xx	xx	x	0
Plates	20,000	90,000	134,000	188,000	347,000
Differential:					
Polynuclear	51.4	45.6	40.0	41.0	47.0
Lymphocytes	41.0	44.4	51.0	49.6	43.0
Large mon's	0.0	1.4	1.0	2.0	2.4
Transitionals	4.6	6.0	3.6	4.6	5.6
Eosinophiles	1.0	0.6	2.4	2.4	1.4
Mast cells	0.4	1.0	1.0	0.0	0.6
Stimulation	0.6	0.6	0.6	0.0	0.0
Myelocytes	1.0	0.4	0.4	0.4	0.0

These examinations present the picture of hemorrhage, and in addition show a remarkably low count of plates in the first few days after the hemorrhage. The number was found to increase steadily until they reached normal on the sixtieth day. One point of interest was the presence of a little blood in the mother's milk occasionally during nursing.

Etiology.—Very little is known as to the cause of this disease. Syphilis and other infections have been blamed frequently. Injury to the floor of the fourth ventricle has been advanced as a cause by Von Pruschen and Pomorski.[9] These latter have been able to support their claim by animal experimentation, but autopsies done on fatal cases of omphalorrhagia do not corroborate their findings. During recent years chemical changes in the blood have been ascribed as causes, and on account of the failure of the blood to clot to any extent it would seem that there must be some chemical change present; but as yet no positive findings have been recorded. From the results obtained from the treatment of the condition by the injection of human serum or by direct transfusion I think that the cause of the condition will be found on complete examination of the serum by the more modern methods of serum analysis. In order to see what it is in the serum of the human blood that causes after a few injections a complete cure of omphalorrhagia I will state the Morowitz[9] theory of coagulation, which is the one most commonly accepted. He believes that there is a thrombokinase from the tissue cells and from the intima of the blood-vessels which by the action of the calcium salts is enabled to act on the prothrombin to form active thrombin which unites with the fibrinogen to form fibrin. The only element according to this theory that is not present in normal human serum is fibrinogen, and it is inconceivable to assume that there is enough fibrinogen present in the serum administered to cause clotting and to cause it permanently. We can, I think, eliminate fibrinogen disturbances as causative of omphalorrhagia. There must be then in these cases some defect in the formation of the thrombin. There can hardly be enough thrombin present in the serum given to cause clotting for the rest of life, and since thrombin is only a product formed after the blood is shed it is not probable at all that the thrombin present in the serum given acts to stimulate the progenitors of thrombin to the perpetual formation of thrombin. Therefore, if the disturbance is in the formation of the thrombin it is to be found in one or more of the following: Thrombokinase, calcium salts, or prothrombin, or its antecedents. Fry[10] has shown that the thrombokinase in fishes, at least, is derived from the tissues alone. He has also demonstrated that the prothrombin is derived from the blood plates. Schmidt,[11] Fuld-Spiro,[12] Loeb,[13] and Morowitz[14] all think that the thrombokinase is derived from the tissues or from the intima of the blood-vessels when injured or from the tissue juices. Howell[15] thinks that the evidence of the presence of such a ferment is not conclusive. Sahli[16] thinks that there is some disturbance of the median thrombokinase in hemophilia. From the manner in which the blood serum was obtained for the injection of my patient, *i.e.* by puncturing the basilic vein with a sharp needle, it is inconceivable that any but a trace of thrombokinase could be present; for the blood did not flow over tissue, and the vessel wall was not injured to any extent. I conclude with reasonable surety that thrombokinase does not play an important part in omphalorrhagia.

There is left for our consideration, then, the calcium salts, and the prothrombin with its antecedents. Calcium salts do not act as curative agents in omphalorrhagia. They have been tried and no good effect noticed. Also in those diseases in which calcium salts do act beneficially they must be given over a long period of time, while in omphalorrhagia the serum need be given only for a short time. For

these reasons I think we can eliminate disturbance of the calcium salts from the etiology. If this reasoning is correct the disturbance is in the prothrombin or its antecedents. This is supported by the examinations that I made of the blood of my case. The white blood cells are not changed more than can be accounted for by the hemorrhage. The same is true of the hemoglobin and the red cells. But the changes in the number of the plates are not accounted for by any reason, excepting the disease. On examination of the table on page 69 it is seen that on the sixth day post partum there were only 20,000 plates found. After the injection of the serum they were found to gradually increase up to normal. The finding of a reduced number of plates would ally this condition with the purpuras instead of hemophilia. In hemophilia there is no change in the number of plates. As has been mentioned above, it has been shown that the prothrombin is derived from the plates (Fry). This reduction in the number of plates is due to over-destruction of plates, or to under-production of them. Should it be due to an over-destruction there must be some toxin or toxin-like substance causing the destruction, and on account of the results of treatment this toxin must find an antitoxin in the serum administered. I can find nothing in the literature to support this assumption either in theory or experiment. From the fact that the amount of serum needed to cure omphalorrhagia for all time is very small it would appear that the condition is due to a diminished production of plates, and that the producton is increased permanently by the administration of serum. The serum in this case acts as an activator. What it is that causes this underproduction of blood plates has not been demonstrated.

AN UNUSUAL CASE OF FIBROID SCLEROSIS OF THE CORPORA CAVERNOSA.*

By M. ZIGLER, M.D.,

New York.

Instructor in Genitourinary Surgery, Post-Graduate Medical School and Hospital; Assistant in Genitourinary Surgery and Dermatology, Lebanon Hospital.

The following is the report of an unusual case of fibroid sclerosis of the corpora cavernosa. The patient is fifty-one years of age, a cigar packer by occupation, and has been married twenty-five years. There is no history of trauma, gout, or diabetes. He had a mild attack of gonorrhea prior to marriage, but denies syphilis. He has three healthy children. Five months ago he came to the Post-Graduate Hospital complaining that intercourse had been almost impossible for several weeks because of severe pain in the penis during erection, and also because of the fact that the distal end of the penis, during the attempted act, bent upward to an angle of 90 degrees toward the abdominal wall. Any attempt on his part to straighten the penis intensified the pain throughout its entire length, but more so at the corona and root.

Physical examination showed two thickened almost calcified plates on the dorsum of the penis. The one was at the distal end, extending from the corona backward over the body of the penis for about two-thirds of an inch. Its width was about one-half of an inch; its thickness, about one-eighth of an inch. The other plate was situated at the root of the penis extending forward about two-thirds of an inch. This posterior plate was the same width and thickness as the interior one. Both plates were hard and tender to palpation. The latter was more so. The examination of the rest of his body was negative. In fact the patient was in excellent health. The Wassermann test was positive plus (+). Treatment: Because of the latter reaction the patient was given iodides. He was started with ten grains of potassium iodide three times a day and kept on this dose for two weeks, after which it was gradually increased, one grain for each dose so that on August 1, 1911, he was taking forty grains three times a day. He noticed that for six weeks past there was considerable improvement in the symptoms, namely, that promptly upon curvature of the penis during an erection he was able to straighten the organ without any pain. He was then able to effect a vaginal entrance and have a successful intercourse. He also noticed that the plates were less tender to palpation. Neither he nor I thought that they had become softer or smaller. September 25, 1911, the patient said that the organ did not curve as much, and he thought the plates were softer and smaller. There was no more pain. The patient was taking seventy grains of iodides three times a day.

Conclusion: I have taken the liberty to report this case because of its rarity, its unusual etiology and its partial response to specific therapeutic measures. Most authorities have considered these cases hopeless, and due to gout, diabetes, or traumatism, and have advised irritating plasters, ointments, etc., locally.

Robert W. Taylor says of local treatment: "Such, however, is the uncertainty of ultimate favorable results that one is not warranted in causing these patients inconvenience or suffering." I do not believe that these plates can be entirely absorbed, neither do I believe that any further improvement can occur. But in view of the fact that this patient had shown considerable improvement under large doses of potassium iodide, and in view of a positive Wassermann reaction, I believe that we have data enough to warrant the assumption that this is a case of fibroid sclerosis of the corpora cavernosa due to syphilis.

The Prognosis of Open Tuberculosis in Childhood.—B. Hahn as the result of an analysis of 133 cases of pulmonary tuberculosis treated at a children's sanatorium found that improvement was noted after a few months in only 22 per cent. of the cases, while only 14.3 per cent. more were improved after a lapse of six years.—*Zeitschrift für die Tuberkulose.*

New York, January 13, 1912.

BANTI'S DISEASE.

SOME fifteen years ago Banti called the attention of the medical world to a singular disease, characterized by a greatly enlarged spleen, presenting a fairly typical pathological picture, and accompanied by a moderate degree of liver cirrhosis, a secondary anemia, and a leucopenia. This disease seemed to him to be a definite clinical picture of unknown etiology. Since Banti's original observation, numerous cases have been published, answering the description of his cases and agreeing with them in the obscure etiology.

In the *Zeitschrift für klinische Medizin* (Volume 74, Numbers 1 and 2) Alexander Neuberg publishes a very instructive case of Banti's disease that was closely observed for three years. The patient suffered from occasional nosebleed, was somewhat anemic, at one time had ascites, which disappeared without tapping, and on physical examination showed a very large spleen, hard in consistency, and a somewhat diminished liver. His condition, so far as subjective sensation and anemia were concerned, improved very much after the use of arsenic, and his general well-being became pronounced enough to make him think of marriage. About that time his blood was tested according to Wassermann technique, and to the surprise of all concerned gave a positive reaction! At once this case of Banti's disease, of unknown etiology and of typical clinical and blood picture, was explained by the existence of congenital syphilis, that diagnosis being somewhat strengthened by a history of several early deaths among the patient's brothers and sisters. Acquired syphilis could apparently be excluded, while the success of arsenic therapy was easily explained by our newly won knowledge of the efficiency of this drug as an antisyphilitic remedy.

This case leads Neuberg to oppose the conception of Banti's disease as a distinct morbid entity. He does not claim that syphilis is the etiological factor in every instance; indeed, he attempts to show that infectious diseases, prolonged gastrointestinal disorders, intestinal autointoxication, etc., may be assumed to have been the causative factors in many of the published cases of Banti's disease. The author insists, however, that Banti's is merely a definite symptomatic group that may be due to many causes. The pathological picture found in the spleen is, according to him, simply indicative of long-standing infection or damage by toxins, while the liver cirrhosis is a secondary phenomenon due to obstruction in the portal circulation by the splenic tumor. The frequent relief obtained by removal of the spleen Neuberg explains by the relief of the portal circulation and not by the disappearance of the primary morbid focus.

Neuberg's paper is very suggestive. It does not, of course, account for the many cases of primary splenomegaly, where no etiological factors can be discovered; on the other hand, it is a step in the right direction in urging clinicians to readjust older clinical observations in the light of recently developed diagnostic knowledge. The Wassermann reaction is, perhaps, one of the most valuable of such modern diagnostic methods, and it should be widely used in the study of chronic diseases of obscure causation.

FINGER-PRINT EVIDENCE.

GALTON, who stood ever for accuracy in scientific procedures, published in 1892 his "Finger Prints," and soon afterward appeared his "Index of Finger Prints." He had reached the conclusion that the chance of the finger prints of two individuals being identical is less than one in 64,000,000,000. Here was indeed circumstantial evidence that would be practically incontrovertible, and so has such evidence in several recent cases been accepted to be. For example, in November last an indictment based solely upon finger-print evidence, which may send a culprit to jail for the rest of his life, was brought by a Grand Jury. The finger prints of the alleged burglar were found upon a pasteboard box and several pieces of silverware that were stolen, these articles being taken to the finger-print bureau in Brooklyn. The prints were duly developed. Shortly afterward the suspected burglar was caught, his finger prints were taken, and they compared precisely with those found on the box and the silverware. Recently again, in a metropolitan court, a burglar had well-nigh established an alibi, but he was held on the only positive evidence against him, that of his grimy finger prints left on a pane of glass which he had removed from the door leading into a loft he had sought to plunder. The expert who demonstrated the evidential value of finger prints at this trial was Lieut. Faurot, the head of the Identification Bureau of the New York City Police Department. In order to demonstrate the conclusiveness of this system, the lieutenant asked the court to pick at random twelve men from among reporters, court officers, and others, who then stepped up and pressed their finger tips upon an inked block. Each imprint having been designated by a letter, one of the twelve was directed to grasp the same pane of glass which the prisoner had removed from the loft. Faurot, who had absented himself during these proceedings, now returned to the court room, when he readily identified the print on the glass with that among the twelve which was lettered "L."

Among further testimony to the merits of the finger-print system which Faurot gave on this trial was that regarding twins, the front and profile in whose photographs were remarkably alike, as were

also their Bertillon measurements. But by their finger prints the two were easily distinguished. The method is now relied on for evidence when photographs and the Bertillon measurements fail.

Once in its history was the finger-print method of identification successfully confuted—for but a brief period, however: A man was charged on suspicion in an English police court with having been found loitering with a felonious purpose in view. A previous conviction was sought to be proved against him by the production of finger prints identical with his from the police records. But he was in possession of papers evidencing that he had served in the army at the time of the alleged conviction, and these being presented he was promptly discharged. However, a week later it was demonstrated beyond peradventure that he had stolen the army papers from another man; besides other marks of identification (such as his handwriting) proved him to be the man with the record which the police had of him.

Many accredit Bertillon with having originated this finger-print system, but it would seem that Galton first indicated and systematized this method of identification, and that when he made it known to Bertillon the latter remained for a long time sceptical as to its validity or utility. Its possibilities of usefulness appear to transcend criminal proceedings. Railways are by this means identifying employees. Banks thus identify foreigners. In the Canal Zone Indians and other government employees who cannot write are thus identified. And in civil transactions there are many who can only sign their names by making "their mark," which is no means of identification at all; but the finger print is both a positive signature and is almost absolutely unforgeable. And such prints endure more than any other mark of the body, unvarying from age to age, and persisting after death, until decomposition. Injuries alone would change them, but the scar of a cut or wound would be an added identification.

SALUTARY EMOTIONS.

Spitzka some years ago estimated that the mortality from wounds in battle is in the defeated army in proportion to that among the victors as four to three or even as three to two. In similar trend Bonnette, a French army surgeon, writes in the *Press Médicale* on the physical intoxication of victory and the extent to which bodily pain can be vanquished by the sense of military triumph. Moreover, the victorious army is not only insensible to its wounds, but it defies disease in like measure; it is the beaten army that succumbs to pain and is the more ravaged by epidemics. The striking illustrations in this paper are drawn in the main from the Napoleonic wars. For example, members of the Old Guard raised themselves on the bleeding stumps of their amputated legs to cheer the Emperor; again, the great Larrey operated without ceasing for thirty-six hours on the wounded soldiers after the battle of Eylau, and emphasized the moral exultation that raised his patients beyond the dominion of pain.

Here is indeed a consideration well worthy the practitioner's attention—the extent to which a reasonable psychotherapy may be adjuvant to material means of cure; and specifically the extent to which such awakened emotions as hopefulness, courage, faith in the surgeon's skill, reliance on the physician's good prognosis will turn the scale in favor of the patient's recovery. One here recalls Meltzer's demonstration of how rich is the animal organism in factors of safety and of rehabilitation; when such emotions as those here noted can be brought to bear upon these factors results oftentimes marvelous and seemingly miraculous may be determined. Nor need one doubt, other things being equal, the accuracy of Bonnette's statement that the victorious army is less prone to such camp infections as typhoid fever and dysentery. In every infectious disease two elements are essential: the presence of the specific germ and the predisposition. A beaten army is a depressed army, and is by that very fact predisposed to infection, while the soldiers of a victorious army become by reason of the stimulus of their victory a barren soil to pathogenic bacteria.

Flatfoot in the Navy.

In the *United States Naval Medical Bulletin* for October last, Passed Asst. Surg. R. G. Heiner, U. S. Navy, discussed flatfoot in its relation to the Navy. During the year 1910 flatfoot was responsible for a greater number of invalidings than any other disease with the exception of tuberculosis. The object of Heiner's paper is to emphasize the necessity for careful examination of the feet of an applicant for enlistment, to show the poor results of treatment of flatfoot patients while they are in the service, and to describe a method of examining which will detect the weak, low, or fallen arches of the feet. That so many men have been passed into the Navy and subsequently been invalided on account of flat feet sufficiently emphasizes the importance of careful examination prior to enlistment. Heiner suggests that there be adopted, as an arbitrary limit of depression of the tubercle of the scaphoid, one-half inch, and would reject all feet below that standard, noting on the figure chart of the enlistment record the distance of the tubercle below the connecting line. It is the depression of the tubercle of the scaphoid to an undue degree when the body is in a certain position that mainly constitutes flatfoot. Heiner concludes that no recruit should be accepted who has eversion of the foot which cannot be corrected by muscular effort, or who has the front of the foot abducted, giving a convex inner border with bulging at the scaphoid tubercle, or whose scaphoid tubercle is more than one-half inch below a line connecting the lower edge of the internal malleolus with the lower tubercle on the head of the first metatarsal bone. Flatfoot is said to be unusually prevalent in America, and has been stated to be owing to the lack of walking exercise in the cities. Among the English, for instance, walking is universal, much more so than in this country, and flatfoot is comparatively rare in England. Whatever the cause of the condition may be, it is well that attention should be called to it, in order that steps may be taken to abate its prevalence.

Nephelometry.

In many physical and chemical reactions a cloudiness of a given medium gives us qualitative information of a definite value. The terminology in use to denote the degree of turbidity is purely relative, much like that employed by meteorologists to denote the degrees of cloudiness of the atmosphere. To determine approximately the absolute degree of cloudiness of media, it is usually necessary to await the full precipitation of the substance causing the same. This may require much valuable time, during which decomposition may occur. Furthermore, the substance in question may not be precipitated, although the centrifuge can be called upon in such a case. To obtain a complete idea of the amount of material which gives rise to cloudiness, we can only depend upon the tedious processes of quantitative analysis. It was inevitable that some attempt should be made to determine rapidly and with sufficient accuracy the amount of matter involved in giving a cloudy reaction. The nature of the Wassermann reaction alone would justify such an attempt. Hence it is not surprising that Zeiss, the well known dealer in optical apparatus, should put forward a nephelometer for medical men. The impetus thereto appears to have been due to Schlesinger (*Berliner klinische Wochenschrift*, October 16), although nephelometers have had a limited field in physics. The optical principles involved are touched upon but lightly in the article cited, and the instrument is not figured. The new instrument promises to be of value principally in milk and blood tests. The amount of fat in milk may be thereby determined. Of more interest are the possibilities of blood reactions, especially in connection with corpuscular studies, hemolysis, and the Wassermann reaction. An instrument of this kind is employed also in estimating the number of bacteria in an opsonic vaccine culture.

A Newspaper Attack on Dr. Park.

A morning newspaper of this city recently attacked Dr. William H. Park, director of the Bacteriological Laboratories of the Department of Health, accusing him of having patented a holding apparatus for pasteurizing milk and then forcing it upon the companies doing business in New York. The facts are that Dr. Park devised a simplified apparatus of the sort, the use of which would effect a considerable saving of money. This was installed in the plant of one company, but when another company wished to use it it was discovered that a man connected with the first company was attempting to get a patent for the process originated by Dr. Park. The latter at once wrote to Washington stating that he never intended to patent the device but wished to leave its use free to all milk dealers. The Commissioner of Patents replied that the only possible way of preventing the other man from obtaining a patent was for Dr. Park himself to apply for one and thus establish an interference. This he did, and obtained the patent about a month ago. Several of the dealers who had put in the apparatus arranged among themselves to pay the cost of the litigation, but thereby secured no rights in the patent. Dr. Park has never received any compensation for his invention, and any person is at liberty to manufacture or use the apparatus without paying royalty to anybody whomsoever. To those who know Dr. Park this is the natural and only possible explanation of the transaction, and it need never have been made but for the unfounded accusation of the newspaper. If this paper had in the first place applied to Dr. Park for an explanation it could easily have learned the facts; but then a sensational story of graft would have been spoiled, and it would be much easier to apologize later or to say nothing.

Retirement of a Veteran Editor.

The announcement is made in the current issue of the *Boston Medical and Surgical Journal* of the retirement of Dr. George B. Shattuck from active editorial management of that publication. Dr. Shattuck became editor of the *Journal* in 1881 and has, therefore, had an editorial experience of thirty-one years, a term exceeded in this country only by Dr. J. Minis Hays of the *American Journal of the Medical Sciences* and Dr. George F. Shrady of the Medical Record and equaled only by Dr. Frank P. Foster of the *New York Medical Journal*. Dr. Shattuck may well be satisfied with this long period of devotion to literary medicine, but his pride must be great as he reviews his work and sees how, under his management, the *Boston Medical and Surgical Journal* has not only maintained the high standards which have always characterized it, but has also steadily advanced in dignity and influence, holding its own with friendly rivals in the front rank of medical journals. It is to be congratulated upon having been guided for these many years by an editor of so many and such great accomplishments, and further that, as it states, it will still have the benefit of his counsel for, we hope, many years to come.

News of the Week.

Health Department's Plans for 1912.—Among the improvements and extension of work planned for the coming year are the following: (1) The grading of the milk supply, including the enforcement of pasteurization as already described. (2) The still further extension of hospital facilities for infectious diseases. (3) The establishment of forty milk stations provided for in the budget of 1912 in addition to the fifteen stations maintained during the past year. (4) The establishment of five clinics for school children. (5) The sanitary control of venereal diseases.

New York Academy of Medicine Undertakes Public Health Work.—At a meeting of the Academy of Medicine on December 4 it was announced that a committee had been formed on Public Health, Hospitals, and Budget, whose work would parallel the activities of the Bureau of Municipal Research in financial matters. The generosity of Mrs. E. H. Harriman has made it possible for the committee to avail itself of the services of an expert statistician. Among the duties of this committee are the organization of a bureau to collect facts in regard to public health, sanitation, and hygiene; to endeavor to establish active cooperation with all public health activities in the city; to keep the medical profession advised of all public health conditions; to render to health, school, and other authorities and to the community at large an authoritative opinion on public health matters; to hold frequent conferences with city officials; to hold public meetings, and to give publicity to the results of the research work of the committee. They will make suggestions and give assistance to the departments in the preparation of their annual budgets

and will make a close and constant scrutiny of hospital conditions in the city. They have already been instrumental in securing funds for contagious hospitals in Queens and the Bronx. The members of this committee are: Dr. Charles L. Dana, Dr. Linsley R. Williams, Dr. W. Gilman Thompson, Dr. John H. Huddleston, Dr. S. S. Goldwater, Dr. L. Emmett Holt, Dr Abraham Jacobi, Dr. J. A. Miller, and Dr. T. C. Janeway

Vaccination Fight in Olean, N. Y.—About 2,000 children have been excluded from the public schools of this town because they have not been vaccinated. The Anti-Vaccination League has offered to defend any person who may be arrested for not complying with the order of the Health Board compelling vaccination. The Anti-Vaccination League has advertised for instructors and proposes to establish a school of its own. There were 40 cases of smallpox in Olean last year.

Vital Statistics of Philadelphia.—The death rate of the city of Philadelphia for the year 1911 was 16.50 per 1,000 of population the lowest figure, with the exception of the year 1909, in ten years. As a result of the enforcement of special measures for conserving the lives of infants, there were 4,604 deaths among children under the age of one year, as compared with 5,232 in 1910. The total number of deaths for the year was 26,092, as compared with 26,879 for the year 1910. There were 14.1 deaths per 100,000 of population from typhoid fever, as compared with 72.4 in 1906, when filtered water first began to be used on a large scale in the city, and with 59.3 in 1907, 34.8 in 1908, 21.1 in 1909, and 17.4 in 1910. There were for every 100,000 of the population 165 deaths from pneumonia, 85 from cancer, 31 from diphtheria, 11 from scarlet fever. There was a decrease in the number of deaths due to almost all of the transmissible diseases, with an increase in the number due to cancer, heart disease, nephritis, and other non-transmissible diseases.

Suicides in 1911.—The record of suicides for 1911 is 12,242, as compared with 12,008 for 1910. The proportion of suicides as between men and women varies but little from year to year. Among professional men physicians head the list, the number being 27, as compared with 51 in 1910, 27 in 1909, and 42 in 1908; clergymen come next, 11 having taken their own lives in 1911. The causes of suicide have been as follows: despondency, 6,114; unknown, 1,480; insanity, 1,052; domestic infelicity, 1,208; ill-health, 1,343; business losses, 153; liquor, 204; disappointment in love, 773. The methods employed were shooting in 4,151 instances; poison, 3,450; hanging, 2,054; drowning, 984; throat-cutting, 604; asphyxiation, 646. Other methods resorted to less frequently were jumping from roofs or in front of trains, burning, stabbing, dynamite, and starvation.

Street Accidents During 1911.—The report of the National Highways Protective Association shows that during the year 1911 there were 423 persons killed and 2,004 injured by vehicles in the streets of New York. This is an increase of 13 per cent. over the fatalities of 1910, when 370 persons were killed and 930 injured. Automobiles were responsible for 142 deaths and 1,031 injuries, an increase of 38 per cent. over 1910. Wagons killed 172 persons. Public taxicabs caused the death of only four persons during the year. Of those killed in 1910, 182 were children under 16 years of age, while for 1911 there was a decrease of 7 per cent. in the number of children killed. The report also shows that there were 88 persons killed and 108 injured at grade crossings in New York during 1911. In New Jersey 43 persons were killed and 118 injured at grade crossings. The crossings of highways at grade resulted in 129 deaths and 226 injuries. The association will try to have a constitutional measure passed by the Legislature fixing the responsibility of chauffeurs and drivers, and they will endeavor to hasten the work of eliminating grade crossings.

The Death Rate in Augusta, Ga.—The annual report of the Health Board of this city, whose population is estimated at 50,000, shows that there were 854 deaths from all causes from November 30, 1910, to November 30, 1911. The death rate for the city was thus 17 per 1,000; of this percentage 13.8 is the white death rate and 22.7 the colored. There were 30 deaths from pellagra reported, 24, or 80 per cent., of which were among the whites and 66 2/3 per cent. were white females, while among the colored population there were no deaths of males and but 6 among the females.

A Plea for the Restoration of the Canteen in the Army.—A meeting of the National League for the Civic Education of Women will be held in this city at the Waldorf-Astoria on the afternoon of January 16, at 4 o'clock, at which "A Message from the Women of the United States Army" will be delivered by Mrs. James B. Burbank, wife of General Burbank of the U. S. Army, and Mrs. Charles F. Roe, wife of General Roe of the U. S. National Guard. Addresses advocating the restoration of the canteen will be delivered by the Rev. William Norman Guthrie, the Rev. Herbert Shipman, Dr. Louis Livingston Seaman, and the Rev. Edward S. Travers, chaplain West Point Military Academy. The Rev. Thomas R. Slicer will preside.

The American Museum of Safety.—The second annual meeting of the American Museum of Safety will be held in the Auditorium of the Engineering Societies' Building, 29 West Thirty-ninth street, on Thursday evening, January 18, at 8.15 o'clock. At this meeting the award of three gold medals will be made as follows: (1) *The Scientific American* gold medal will be awarded to the most efficient safety device invented during the last three years and exhibited at the museum's exhibit hall. (2) The Travelers Insurance Company gold medal will be awarded to the American employer who in the judgment of the American Museum of Safety has done the most for the protection of the lives and limbs of his workmen, by means of safety devices for dangerous machines and processes. (3) The Louis Livingston Seaman gold medal will be awarded for progress and achievement in the promotion of hygiene and sanitation, and the mitigation of occupational disease.

The Use of Common Towels Forbidden.—The New York City Board of Health, at its meeting January 4, adopted a resolution amending the Sanitary Code to forbid the use of common towels. The new section of the Code reads as follows: "No person, firm, or corporation having the management and control of any public lavatory, washroom, or public comfort station shall maintain in or about such lavatory, washroom, or public comfort station, any towel or towels for use in common."

Suicide by Quinine.—A young woman in Newark, N. J., killed herself recently by taking 188

grains of quinine, swallowing ninety-four two grain pills. She was driven to take her own life, it was said, by despondency following an operation for appendicitis three weeks ago.

The German Tramp Epidemic.—It is reported that the mysterious and fatal epidemic, which killed over seventy-five hoboes in Berlin at Christmas time, has appeared in Leipsic and Hamburg. The nature of the disease is still a matter of dispute, some regarding it as of bacterial origin, others maintaining that it was simply methyl alcohol poisoning. It is said that the International Sanitary Commission has been asked to investigate and make an official report on the disease.

Fewer Accidents in Mills.—The fatalities in the mills of the Pittsburgh district were reduced by 30 per cent. during the year 1911, there being 289 fewer deaths from mill accidents than in 1910. This decrease is directly due to the installation of safety devices.

Philadelphia Will Segregate Vice.—The reform administration of Philadelphia, after conferring with prominent clergymen, have declared officially that the social evil will not be tolerated in the city, but they have issued orders that resorts will be allowed to exist in certain parts of the city under strict police supervision. Police inspection of the restricted district will include hourly visits by uniformed men to see that no liquor of any description is sold and that no intoxicated men are allowed to visit them. The ordinance forbids the keeping of liquor in the houses, even for medicinal purposes.

Milk Regulations Amended.—The Board of Health of New York has amended its regulations regarding the classification of milk by requiring all milk dealers in the city to inform the department on or before January 18 what grade or class of milk they intend to sell. It is provided that no milk shall be sold under grades A (for infants and children), B (for adults), C (for cooking and manufacturing purposes only), or as condensed, skimmed milk, or concentrated milk, or modified milk, without a permit from the Board of Health, but an exception is made of hermetically sealed cans.

A United Medical School for the University of California.—Plans for the amalgamation of the various departments of medical instruction under the supervision of the University of California were adopted on December 22, 1911, at the meeting of the Board of Regents. It was decided to adopt the plan of securing paid instructors for clinical subjects, instead of relying upon practising physicians. The principal chairs of medicine, surgery, and obstetrics will be held by professional instructors, who will devote their whole time to teaching or research work.

Model Tenements Opened.—The East River Homes, a group of model apartment buildings located at Seventy-seventh street and the East River, were opened for inspection on December 5. The buildings were made possible through the generosity of Mrs. W. K. Vanderbilt, who invested $1,300,000 in the project. These buildings cover eighteen city lots and contain 383 apartments of from two to five rooms each. They were built for the purpose of providing homes at a reasonable price for persons afflicted with incipient tuberculosis or those who are delicate and predisposed to the disease, and offer all the advantages of a country sanatorium. The special features of the buildings are the liberal use of white glazed tiling and concrete, the avoidance of angles between the baseboard and floors, the outside staircases with many resting places, the utilization of the space usually given to halls and stairways for additional space in bedrooms. The roofs are fitted up as a garden and playground, and it is planned to fit some parts up for laundries. Each suite of rooms has its own bath, electric light, heat, and hot water included in the rent, which ranges from $1.25 to $2 per room per week. The trustees, of whom Dr. Henry L. Shively is president and Dr. Walter B. James vice-president, believe that these apartments will not only pay their carrying expenses but will pay 4 per cent. on the investment.

Harvey Society Lecture.—The seventh in the present course of lectures will be delivered by Professor Henry Fairfield Osborn of Columbia University on January 20 at 8:30 in the New York Academy of Medicine. The subject will be "Unit Characters in Heredity as They Appear to a Paleontologist."

Chattahoochee Valley Medical and Surgical Association.—The eleventh semi-annual session of this association will be held at LaGrange, Ga., Tuesday and Wednesday, January 16 and 17, 1912, under the presidency of Dr. L. W. Johnston of Tuskegee, Ala. The secretary of the association is Dr. W. J. Love of Opelika, Ala. Place of meeting, Elks Home.

Harvard's New Medical Plant.—When the buildings now under construction are completed there will be sixteen institutions forming the plant of the Harvard Medical School. These will represent a money value of $20,000,000. The six following buildings are in various stages of construction: the Harvard Memorial Cancer Hospital; the Thomas Morgan Rotch, Jr., building, which will house the Infants' Hospital; the Children's Hospital, which will cost $500,000; the Peter Bent Brigham Hospital, which has a fund for buildings and maintenance combined of $6,000,000; the State Psychopathic Hospital, which has an appropriation of $600,000 for grounds and building, and the Robert Brigham Hospital. There is also a project on foot to erect a Harvard dormitory and medical union clubhouse to be conducted on the same principle as the Harvard Union and dormitories, but exclusively for medical and dental students.

Large Hospital for Pittsburgh.—On January 1 the West Penn Hospital in Friendship Park was opened for public inspection. The main building is six stories high, with four wings each four stories high. It will accommodate 500 patients, and every room is an outside one. With equipment and furnishings there is represented an investment of $1,025,000.

A First Aid Hospital.—At Collinsville, Ill., an underground emergency hospital has been opened in a very large coal mine. The hospital is built in the heart of the mine and is designed to give first aid to the injured.

Bushwick Hospital of Brooklyn has been sold for $75,000 and plans have been filed for the erection of new buildings on a site which the hospital owns at the corner of Howard and Putnam avenues. It is expected that the new building will be ready for occupancy in the fall of 1912.

Dr. Blue to be Surgeon-General.—President Taft has sent to the Senate the nomination of Dr. Rupert Blue of South Carolina as surgeon-general of the Public Health and Marine-Hospital Service, succeeding the late Dr. Walter Wyman. Dr. Blue is a graduate of the Medical Department

of the University of Maryland in the class of 1892 and entered the service in March, 1893. His great work was the eradication of the plague from San Francisco. He has recently been stationed at Honolulu. In announcing the appointment, President Taft gave notice that hereafter the term of service of the surgeon-general shall be limited to four years.

Dr. Edward M. Looney, resident physician at the Deer Island house of correction, has been appointed Assistant Port Physician of Boston.

Dr. T. H. Frazer of Mobile, Ala., has been appointed as acting dean of the faculty of the Medical Department of the University of Alabama to succeed Dr. Rhett Goode, deceased.

To Honor Dr. John Morgan.—A proposal has been made to honor Dr. John Morgan, the founder of the Medical School of the University of Pennsylvania and the father of medical education in the United States, by erecting a memorial tomb, wherein his remains will be laid. It is claimed that Dr. Morgan's school antedated that of Harvard, having, together with Dr. Shippen, Jr., begun the systematic teaching of medicine in 1765 and having been elected in the same year to the Chair of Theory and Practice of Physic at the College of Philadelphia. Dr. Swithin Chandler was chairman of the committee appointed to investigate these claims, and the committee has reported that they are well founded.

Obituary Notes.—Dr. Richard R. Rogers, a graduate of the University of Pennsylvania in 1862, died at his home in Trenton, N. J., after an illness of three weeks. He was county physician for fifteen years.

Dr. Frederick D. Mitchell of Pawling, N. Y., a graduate of Bellevue Hospital Medical College, class of 1880, died at his home December 29, 1911, at the age of 53. He leaves a widow and one son. Dr. Mitchell began practice at Poughquay and came to Pawling twelve years ago.

Dr. Silas D. Black, known as the "Nature Poet," died in Los Angeles, Cal., on January 2, at the age of 60 years. He practised in Decatur, Ind., until three years ago.

Dr. James Lyman Belknap of Wolfboro, N. H., died from shock following a surgical operation at the Massachusetts General Hospital on December 29, at the age of 36 years. He was graduated from Dartmouth College in 1898 and from the Harvard Medical School in 1902. He was formerly assistant resident physician at the Massachusetts General Hospital.

Dr. James Warwick of Clinton, Mass., died suddenly on December 28, at the age of 68 years. He was born in England and was graduated from the Albany Medical College in 1877. He was a surgeon in the British Army for nine years and a member of the British Military and Naval Association.

Dr. M. Louis Weil, a graduate of Bellevue Hospital Medical College, New York City, 1889, died at his home in New York on January 3, at the age of 53.

Dr. Algernon Coolidge, Jr., a descendant of Thomas Jefferson, died at his home in Boston on January 4. He was 82 years of age.

Dr. Charles Emil Dohme, at one time president of the American Pharmaceutical Society and president of the Maryland College of Pharmacy, died on December 7, at the age of 68.

Dr. A. H. Read of Opelika, Ala., died suddenly on December 27. He was born in 1836 and graduated from Oglethorpe Medical College, Savannah, in 1858.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE MASS MEETING IN LONDON ON THE INSURANCE ACT.

London, December 22, 1911.

The Insurance Bill is now an Act, the Royal assent having been given on Saturday by commission. On Tuesday came the great mass meeting of the profession in London to protest against its provisions. "Seems rather a day behind the fair," does it not? But that is unquestionably the fault of the Council of the B. M. A., which assumed the leadership and was left to carry out the campaign. The meeting was a large one, crowding the Queen's Hall, was in deadly earnest, and practically unanimous. Elder practitioners declare they have never known such unanimity and juniors say this will only be the beginning. It was certainly a strange experience to find a great hall crammed with doctors shouting excitedly their determination to fight to a finish. It must be admitted that the proceedings were not exactly orderly, but afforded a vivid contrast to the deadly dulness that often characterizes medical meetings. This one began and ended with singing "Rule Britannia," the chorus of which, "Britons (doctors) never shall be slaves," was given with full strength of voice and lungs.

Sir Watson Cheyne took the chair and said the act had become the law of the land and soon insured persons would be asking for free medical attendance promised by the Chancellor of the Exchequer, but for which he has made no arrangement with the profession to provide it. Their terms had been stated to him again and again, but were not visible in the act, but ignored or shelved or handed over to outside bodies. They were there to say they wanted no more of the Chancellor's specious promises and refused to do as he desired until their demands were agreed to in a form that rendered further quibbles impossible. It was nonsense to pretend they refused to attend the poor—they would continue to do so, as they had always done, until their terms were granted; his terms would never be accepted. The act, as it stood, meant ruin to hundreds, aye thousands, of their brethren. To be united they must, he thought, stick to the B. M. A., the only organization they had for such work, even if they found the fault was in the Council. (Here were cries of "Turn them out.") He had no brief for the Association, in fact he had left it on account of certain unsatisfactory doings, but he appealed to them at this crisis not to follow his example lest it should cause disunion.

Dr. Fred J. Smith moved the first resolution, practically that of the Manchester meeting, reported in my last week's letter. He subjected the circulars of the B. M. A.'s Council to stringent criticism and convicted them of misleading statements. He anticipated nothing but undignified wrangling between the Insurance and Medical Committees. As to income limit, it was not conceded but he had strong evidence it would have been, only their negotiators were afraid it would be some risk to the government, so they sacrificed their profession instead. The Association had told their Council to get their six points or die in the last ditch. They had not died in that ditch, but flung their medical secretary therein to appease the appetite of the Chancellor of the Exchequer.

Mr. Milton Townsend seconded, and impressed on the audience that the meeting was not for a mere pious opinion. They would be asked to sign a requisition—the first step in a campaign. If they stood firmly together they could compel the government to grant their demands or drop the medical provisions in the act altogether. The resolution was about to be put when Sir Victor Horsley rose and asked a question which could not be heard completed on account of the angry cries which arose. He was invited to the platform and on the way was assailed with hissing, booing, and cries of "traitor." On the platform he stood for three or four minutes while the chairman's appeals for order were drowned in hostile shouts. Some cried "shame" and "hear him." One called out: "No other shall be heard until he has spoken." In an interval the chairman asked: "Are you afraid of what Sir Victor Horsley has to say?" but this brought fresh taunts of "He's a traitor." The chairman replied: "I must insist; you are spoiling the meeting," and was supported by some asking for "fair play," though their voices were scarcely heard for shouts of "We don't want to hear him," and "Go home; did Lloyd George send you?" etc. The chairman's tact at length prevailed and Sir Victor spoke for a few minutes. He had nothing very irritating to say, his point being that the resolution was inaccurate, as the representatives had not ordered the Association to accept only the six points, but if they could not get all in the bill they were to get all they could and settle the others with the commissioners. The resolution was then carried, only two or three hands of the vast audience being held up against it.

Mr. Raiment moved the second resolution, which reasserted the demands of the profession and held that everyone should refuse to take office until they were secured. He said boycott the act until the six points were conceded or the medical provisions dropped or a third alternative left them to make their own arrangements with the insured. It had been said government could appoint their own whole-time doctors. That would require 7,500 doctors at £600 a year at least, and each would have to attend 120 patients a day in summer and double as many in winter. They were charged with splitting the Association, but boycott was the original policy of the Association.

Dr. Arthur Helme of Manchester, seconding, said he was there to tell them the men of the North would stand by them in determining not to form panels of doctors under the act. That did not wreck the act, as the B. M. A.'s president of Council had said, and he threw back the words in his face. They were not refusing to work under the act on any terms; they offered on their own terms. They would give their own charity to the poor, not let Lloyd George dispense his at their expense. They could arrange an efficient medical service for the poor which would be absolutely under medical control. In this crisis the B. M. A. had failed them. Drs. Pinder, Brierley, and Hart, all of Manchester, followed with powerful speeches, showing how united is the North. So is the country generally, for Liverpool, Birmingham, Scotland, and even Ireland sent supporters to this London meeting.

Dr. Keay, member of the Council of the B. M. A., said no member of that body could object to the resolution, but in social legislation much was generally left for commissioners to deal with. He was heard impatiently and the resolution was carried unanimously, after which, on the proposal of Dr. Sydney Phillips, seconded by Sir John Tweedy, it was decided to send copies of the resolutions to the Prime Minister and Chancellor of the Exchequer. Copies of a requisition from members of the B. M. A. present, calling for a general meeting, were handed around and numerously signed.

After the meeting Sir Victor Horsley, Dr. Keay, and Dr. Rice-Oxley, three members of the Council of the B. M. A., who attended the meeting, issued a statement of what they had desired to say. Their chief point is that the resolutions passed express substantially the views of the Council and they conclude that they ascribe to "ignorance alone and not to intentional discourtesy the unfortunate intolerance" at the Queen's Hall.

The Scottish profession has had its say. A meeting in Glasgow on Saturday, attended by practitioners from all parts of Scotland, decided on an attempt to work under the act on condition that the six points of the B. M. A. were granted; otherwise not. Further, it was resolved to ask the Association's Central Council to strengthen the Scottish committee, give it executive power for Scotland, for which it was desired that a paid secretary with an office should be appointed.

The *Practitioner* received in five days 20,712 answers to the referendum sent out, as stated in my last letter; 20,149 answered no, 352 yes, and there were 211 queries. The *Practitioner* is following this up with a circular to the entire profession, asking a pledge not to accept any service under the act, providing that at least 23,000 combine in this promise.

The newly formed Medical Union meets to-day in Manchester to discuss a scheme for raising half a million sterling as a guarantee fund to help practitioners who may suffer from refusing to work under the act. It is hoped the B. M. A. and all other medical organizations will cooperate.

At the instigation of the Chancellor of the Exchequer the commissioners under the act, although not formally appointed, issued last night a preliminary memorandum to serve as some guide to the position of societies and other bodies affected, pending the compilation of a comprehensive memorandum at a later date, which they hardly expect to complete before February.

The Friendly Societies are taking steps to prepare for working under the act. Some of them hope to improve it by obtaining later such amendments as may be found necessary by experience. The grand master of the Manchester Unity, which has nearly 700,000 members, said the other day that if they foamed at the mouth and used all the adjectives possible it would not alter matters. Therefore the easiest course was to do their best to understand it and see how they could adapt it to their requirements. None of them wanted it, but he advised them to become an "approved society," as they could then retain their present investments and effect a saving in management expenses.

The National Deposit Friendly Society, with some 230,000 members and funds amounting to £1,400,000, has definitely determined to become an approved society under the act.

The sinister hope of some is expressed in the official journal of the Foresters' clubs, which assures its readers that the medical agitation is only "idle chatter that need not seriously be reckoned with," and goes on to declare that the doctors concerned "will certainly not resign or throw away

their living at the behest of the agitators attached to the British Medical Council." But what if these doctors have learned something from the tactics of the clubs in the past?

I have filled my space with a single subject, and touched on only part of that. But you must understand that it is the only thing that doctors here have cared to talk about these few days. Even old Father Xmas is being put into the shade and gets a bare mention between the disputed points that absorb medical attention.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

WASSERMANN'S CHEMOTHERAPEUTIC EXPERIMENTS ON CANCER—THE ELECTIVE DESTRUCTION OF MOUSE CANCER BY MEANS OF COMPOUNDS OF SELENIUM AND EOSIN—TOXICITY OF THE LATTER—RESULTS DO NOT WARRANT THE APPLICATION OF THIS METHOD IN HUMAN BEINGS.

BERLIN, December 20, 1911.

THE meeting held to-day by the Berlin Medical Society promises to rank among the most noteworthy that have been held in the past. For at this meeting Wassermann, in conjunction with Hansemann, presented their paper, entitled "Chemotherapeutic Experiments on Cancerous Animals," from which it would appear as if a long stride has been taken forward in the solution of the problem of the elective attack on tumor cells by way of the blood-stream.

At the outset Wassermann states the problem in its simplest terms: "Is it possible in the body to cause an elective destruction of the tumor cells without affecting the other cells of the body?" This is an aim that has not yet been realized. Of course, it has been possible, by means of the injection of any one of a large variety of substances directly into the tumor mass, to bring about the latter's destruction. But, in order that one might obtain a strictly elective action, it would be necessary that the active agent should circulate in the blood. With this end in view, Wassermann employed substances with known biological properties, such as, for example, cobra venom, which is known to act upon the cellular lipoids. From his investigations, however, it was found that the substance sought for would have to be a stronger one than is produced from biological sources. It was also discovered that well-developed mouse tumors do not undergo spontaneous absorption. In order to determine whether the serum of healthy individuals possesses a stronger destructive action on cancerous tissue than the serum of an individual suffering from cancer, cancer tissue was placed in such sera, respectively, and, with the aid of tellurium salts as suggested by an Italian investigator, it was sought to determine whether any of the cells were destroyed. This experiment was fruitless, so far as the aim sought for was concerned. Nevertheless, it showed that the tellurium salts were deposited in the cell-nests in the vicinity of the nuclei. This was also true of the salts of selenium. These metals were therefore deposited in the regions of the maximum cellular activity; this is particularly significant in the case of tumor cells, which have a most active metabolism, particularly in the nucleoplasm. Local injections of selenium and tellurium into mouse tumors, in fact, brought about their dissolution, but intravenous injections did not have this effect. In the search for a substance that would rapidly carry the selenium to the locality of the tumor, without the selenium at first being anchored by the other cells of the body, Wassermann hit upon the idea of combining this drug with the highly diffusible fluoresceins. After a series of painstaking experiments, more than two hundred new compounds being produced and tested, Wassermann at last succeeded in getting a combination of selenium and eosin that appeared to be effective. At present this preparation occasionally varies in its uniformity. A quantity of two and a half milligrams kills a mouse. In some cases, however, the animal can tolerate a relatively large dose. In selecting animals Wassermann chose those with hard tumors having a size no smaller than that of a grape. One injection was given daily for three days, and on the fourth day was omitted. On this day a distinct softening of the tumor was observed. On the fifth day another injection was given and the tumor became a cyst. After another day's pause a further injection was followed by a diminution in the size of the cyst, which sometimes disappeared entirely. But, as a rule, seven or eight injections were necessary to produce a complete cure. Particularly to be noted is the fact that frequently in the stage of absorption of the tumor the mice died, apparently because they were not adapted for this intensive process. It was also shown that, in cases in which a complete cure had not taken place, a recurrence of the growth was quickly manifested. The preparation was employed not only in experimentally produced tumors, but also in those occurring spontaneously, with success in both cases. One of the mice is still living, three months after the disappearance of the tumor. Wassermann emphasizes the fact that his results have been obtained only with mouse tumors and only with the particular strains with which they have experimented.

Hansemann describes in detail the microscopic changes occurring in the tumors. During the process of resorption the cellular remains are found mostly in the spleen and only slightly in the liver. Metastases from these organs have never been observed. That the rapid resorption of tumor masses corresponding to one-half of the original weight of the mouse subjects the latter to considerable danger is easily understood. If the selenium preparation is injected into healthy animals, the spleen becomes swollen and distended with lymphatic elements, the follicles lose their distinct contour, and lymphomata appear; but these in no way harm the animal. The drug is therefore harmless, so far as the changes produced in the organs are concerned. If the mouse succumbs, this is merely because of the toxicity of the drug. Hansemann also points out that mouse tumors and human tumors are not the same, and that his findings would not warrant one in applying this drug in the treatment of human beings.

The Popliteal Incision for the Removal of "Joint Mice" in the Posterior Capsule of the Knee-Joint. A Report of Cases. E. G. Brackett and R. B. Osgood.

A Review of Ten Years' Work in Anesthesia. F. Allen.

A Preliminary Note on Intravenous General Anesthesia. A. M. Dodge.

A Parasitic Multilocular Ovarian Cyst Weighing Ninety Pounds. P. E. Truesdale.

"Joint Mice" in the Posterior Portion of the Knee-Joint.—E. G. Brackett and R. B. Osgood report four cases in which "joint mice" and foreign bodies in the poste-

rior portion of the knee-joint were removed by means of a popliteal incision.

Ten Years' Work in Anesthesia.—F. Allen states that at the Massachusetts General Hospital no one anesthetic agent is pushed to the exclusion of others. Successful anesthesia requires careful preparation on the part of both patient and anesthetist. Indispensable in every surgical procedure of magnitude, in gas and oxygen anesthesia, and also in spinal anesthesia, is the preliminary use of morphine, atropine, and sometimes hyoscine. For the control of difficult subjects, *i.e.* plethoric, alcoholic, athletic, or obese people, the author gives large preliminary doses of morphine and atropine, induces anesthesia with A. C. E. mixture or anesthol, putting the patient under rather rapidly in order to avoid a stage of excitement, and maintains anesthesia with ether on a semi-open inhaler, possibly giving chloroform or C. E. again toward the end of the operation. A very useful maneuver in these cases is to use nasal tubes. The author also uses the closed method of etherization whenever he can, but chiefly in gynecological patients or in easily controlled patients of either sex. In heart cases he generally uses the A. C. E. ether sequence with oxygen. He believes that nitrous oxide and oxygen is the safest anesthetic if restricted to momentary administrations.

Intravenous General Anesthesia.—V. M. Dodge states that the originator of this method, Burkhardt, usually employs three solutions: (*a*) physiological salt solution; (*b*) physiological salt solution containing 5 per cent. ether, and (*c*) physiological salt solution containing 1½ per cent. isopral. Although in some cases the isopral solution was not used, the routine was to start the anesthesia with it and continue with the ether solution. These solutions are contained in large burettes, all connected by rubber tubing to a glass cannula, which is introduced into the vein in much the same manner as for the intravenous use of salvarsan. Any superficial vein may be used, but as a rule the median basilic of the left arm will be found the most convenient. Anesthesia is induced somewhat more rapidly than by inhalation, and after it is complete the plain salt solution is alternated with that containing the ether according to the depth of anesthesia required. As a rule, less than half the amount of ether used by inhalation is necessary, and the patients recover with the customary unpleasant after-effects of ether absent or much mitigated. Intravenous anesthesia is indicated in operations about the head and neck, in hemorrhage, in weak cachectic patients, in diseases of the respiratory tract where inhalation anesthesia is objectionable, etc. It is contraindicated in nephritis, extreme arteriosclerosis, severe heart lesions, plethoric patients, etc. In the author's opinion, its chief field of usefulness will be found in operations about the head and neck, in which it is desirable to have the anesthetic and anesthetist removed from the surgical field, and here it would seem to be the method indicated in a majority of cases.

Ovarian Cyst.—P. E. Truesdale reports a case of multilocular ovarian cyst, in which the tumor removed at operation weighed ninety pounds.

A New Method of Percussion. O. Lerch.

Typhoid Fever Traced to Bacillus Carrier.—C. F. Bolduan and W. C. Noble report an outbreak of forty-four cases of typhoid fever in New York City traced to the milk supplied by a farm on which there had been six cases of typhoid fever in 1904, one case in 1907, and one case in 1908. The dairyman handling the milk on this farm represented the last of the six cases in 1904, and was now the only person on the farm who had had the disease. Specimens of his stools were collected and examined for typhoid bacilli. The examinations disclosed the presence of enormous numbers of living typhoid bacilli; in other words, the man was a bacillus carrier.

Venereal Diseases and Infant Mortality.—P. A. Morrow states that syphilis is the only disease transmitted to the offspring in full virulence, killing them outright or blighting their normal development. This is shown not only in the lack of vitality, but also in the incapacity of resistance to disease. The chances of an infected child dying under fifteen years of age are nearly seven times greater than that of the child free from syphilis.

Sterility in Women.—E. McDonald discusses the treatment of this condition. A spare diet is conducive to conception, and likewise open-air exercise. The patient should be instructed as to habits of coition, all of which should combine to allow the seminal pool to remain in the posterior vaginal fornix as long as possible. A preliminary alkaline douche favors the vitality of the spermatozoa. In the treatment of sterility it is necessary to treat the special conditions that may cause it. If the vagina cannot retain the seminal fluid the posterior fornix should be stretched by means of a ring pessary or by tampons. A conical, elongated, stenosed cervix should be dilated with the small steel dilators of Starlinger. In the case of an infantile uterus a hard rubber stem pessary should be inserted under anesthesia, but preceded by a course of dilatation of the cervix for at least a couple of months. In this condition also electrical treatment by means of the galvanic current is of value. With the sterilized negative electrode in the uterus 50 milliampères are applied for five minutes at a sitting, combined with gentle massage, two or three times a week. If these measures fail it may be necessary to enlarge the internal os by operative means, of which the Pozzi-Fenwick operation is the best. In cases of decreased menstruation and approaching premature menopause the administration of lutein extract is of value.

Diffuse Suppurative Labyrinthitis.—J. Auerbach notes the following symptoms of this condition: spontaneous nystagmus, dizziness, disturbance of equilibrium, disturbance of vestibular irritability, and disturbance of hearing. In differential diagnosis the nystagmus should be distinguished from the optic, congenital, neurasthenic, cerebellar, and meningitic forms. Dizziness may be caused by neurasthenia, heart disease, arteriosclerosis, toxemia, or tabes.

Climates of the Southwest.—E. E. Elliott points out the great variety of climates that may be found even in limited areas of this region. From Denver on, all towns in northern New Mexico and northern Arizona are in the mountains and, therefore, of more or less great altitude, varying from 5,000 to 7,500 feet above the sea level, while the towns in the extreme southern portion of New Mexico and the southern half of Arizona are south of the high ranges, and therefore of lower level, running from 1,100 to 4,000 feet. This slight difference in latitude and marked difference in altitude produce distinctly different weather conditions throughout the year. The entire region, however, is comparatively dry. The winters in the more northern towns are necessarily more or less severe at times with snow, wind, and occasional intense cold, but the air is usually clear and bracing. The winter season is not nearly as long or severe as in the northern or eastern States. The summers and autumns are cool and delightful and usually free from high winds. The winters in the southern section are warm (with the possible exception of a few weeks), dry, and free from high winds. The sum-

mers are unbearably hot. This section includes all towns to the south from El Paso to the mountains near the coast of California. The maximum amount of outdoor living is possible for about eight months of the year.

Radical Operation in Frontal Sinusitis.—S. McCullagh states that in acute frontal sinusitis one should never operate unless it is impossible to obtain drainage by intranasal treatment, surgical or otherwise, or unless some complication arises that makes operation imperative. In chronic frontal sinusitis one should operate immediately in any case in which any of the following complications exist or threaten: cerebral abscess, epidural abscess, meningitis from extension, orbital cellulitis or abscess from extension, cellulitis or fistula due to perforation of the anterior wall of the sinus, necrosis, osteomyelitis, septicemia in the presence of any fundus change apparently due to the infection in the sinus, and in which malignant disease is suspected in the sinus. One should operate in every case where the allied conditions are such that much intranasal surgery will be required to obtain good drainage. One should operate when the symptoms point to or the *x*-ray plate shows marked involvement of the sinus, even though the ethmoids be but slightly involved and the obstruction to drainage removal by a slight intranasal operation, when circumstances are such that a prolonged course of treatment is impracticable. One should operate in any case in which toxemic symptoms are not promptly relieved by real or apparent relief of obstruction to drainage and appropriate local treatment.

Care of Crippled Children.—D. C. McMurtrie states that every effort should be made to inspire confidence in the crippled child, who should be encouraged and made to do all his abilities show. The crippled child needs normal training plus the special aid required to offset the handicaps imposed by his deformity.

Percussion of the Kidneys.—O. Lerch calls attention to the main points of his method of percussion of the kidneys, as described by him in MEDICAL RECORD, Vol. 79, page 201.

Senile Mental Confusion and Delirium.—C. W. Burr describes the transitory mental confusion and delirium of old persons and attributes the symptoms to poisons carried by the blood rather than to the hardening of the arteries. The thickened arteries are often a mere local sign and there are indications of the action of a pathological process disturbing or destroying the proper working of all the important organs. Cerebral arteriosclerosis may be marked without any mental symptoms.

Lateral Spinal Curvature.—E. A. Rich has attempted to gain correction in this condition by means of lateral suspension and a figure-of-eight molded splint maintaining a steady pressure on the desired point of counterpressure on the pelvis and neck. This, however, is practicable only in children under ten or twelve. Employing much the same principle in another way for the older patients, he makes a light mold of the patient standing up and slightly suspended. This is later filled with plaster giving one a torso the exact replica of the patient. The torso thus made is lengthened in the waist and corrected much as described by Lovett and Sever. On this torso is made a plaster or celluloid jacket that fits over the corrected shoulders and neck. The jacket is removed from the torso by lateral incision on the side opposite the great curve and after completion buckled together again over the patient. Large areas on the side of the concavity can be removed from the jacket to allow greater freedom where pressure is not needed and to lighten the jacket. As the jackets cease to exert pressure more and more of the mass representing the curve and the rotation of the ribs is shaved off the torso and a corresponding amount of new plaster of Paris added to the opposite side, and on this further corrected torso new jackets are made.

Hypodermic Outfit.—H. Crenshaw describes an outfit that consists of a cylindrical vial about 4 inches long and ¾ of an inch in diameter; a perforated cork; an all-glass syringe with ground-glass piston; a platinum needle; and about one ounce of sterile water. The platinum needle of the syringe is inserted snugly through the perforated cork until the flange on the back end of the barrel rests against the cork. The vial is then nearly filled with the sterile water and the cork (with the syringe passed through it) is inserted into the mouth of the vial.

Varicose Veins During Pregnancy.—A. J. Gilmour reports a case of marked varicose veins of the right leg in a patient six months pregnant.

Preparation of Agar.—W. F. Thompson describes an improved method of preparing agar.

Venoperitoneostomy for Relief of Ascites.—H. E. Castle offers a modification of Routtе's operation of anastomizing the saphenous vein to the peritoneum for the relief of ascites. The curved incision in the upper part of the thigh prevents kinking of the vein. The author's method of anastomosis makes it possible to have the suture at a sufficient distance from the lumen of the vein to prevent any obstruction or obliteration of it. The subcutaneous transplantation of the vein reduces the formation of cicatricial tissue about it to a minimum. Anchoring the omentum prevents its contact with the anastomosis.

Appendiceal Crushing and Cutting Forceps.—S. C. Glidden describes a forceps whose longitudinal serrations crush the tissue of the appendix to a paper-like thinness, removing all fecal matter from the portion crushed. A sliding knife blade, buried in the point of one blade of the forceps, rises along the center as the ring between the forceps handle is pulled on, causing it to cut clean, leaving the appendix stump sealed ready for invagination. The part of the appendix which is removed is also sealed at the cut surface, preventing leakage of any fecal matter on the wound surface or sponges. The forceps first crushes and then cuts. It has also been used in removal of ovary and tube, as it leaves a clean incision, which is usually whipped over with a line of sutures.

External Dislocation of the Knee.—R. H. Fowler reports a case of this condition.

Cog-Wheel Resistance of the Extremities in Paralysis Agitans.—H. N. Moyer states that this sign is elicited by the examiner grasping the wrist with one hand and steadying the arm with the other above the elbow. Rapid flexion and extension of the arm are made. Instead of an even movement, without resistance, when there is no involvement of motility, one, two, or perhaps three slight hindrances to the movement are experienced by the examiner, which communicate to the hands of the examiner a jerky feeling. This is not sufficient to stop the movement of the extremity, so that it may be seen, but it is readily appreciated by the hand of the examiner. After the ex-

tremity has been passively moved for a short time the jerks will slowly disappear, to be followed by a return after a period of rest. The symptom is most easily elicited and is most commonly present in the upper extremity, though it is occasionally noted in the lower. When testing the leg the same method is pursued as when examining the arm, the patient being conveniently seated on a table and the leg rapidly flexed and extended at the knee. This symptom belongs to the early period of rigidity in Parkinson's disease, and it is this fact that gives it its value from a diagnostic point of view.

Abuse of Normal Salt Solution.—G. H. Evans states that the apparent harmlessness of sodium chloride has led to its misuse, the capacity of the kidneys to eliminate it being altogether too much overestimated. The toxicity of sodium chloride in large quantities has been abundantly demonstrated and the prevalent use of this remedy in cases of toxemia due to acute infections accompanied by marked diminution or absence of chloride excretion deserves condemnation. The harm resulting from large amounts of water introduced is probably even greater than that produced from the effects of chloride retention.

Baby Tents.—By F. W. Allin. (See MEDICAL RECORD, Vol. 80, page 49.)

The Leucocytes in Tuberculosis.—W. W. Watkins finds that the percentage of lymphocytes affords an apparently reliable indication of individual resistance to tuberculous infection. In healthy adults he found an average lymphocyte count of 41.5 per cent. and in none a count less than 29 per cent. Thirteen patients definitely cured of tuberculosis gave an average count of 45 per cent., while in advanced or progressive cases the averages were not over 24 or 25 per cent. In patients who have recovered there seems to be an increased percentage and in normal individuals it seems to be increased by high altitudes and absence of moisture and of high temperature. In the beginning of active tuberculosis there seems to be a slight increase, continuing as long as the lung tissue maintains its resistance. The blood of tuberculous patients with lymphocytosis differs from normal blood. The large mononuclears prevail but are different from the ordinary large ovoid lymphocytes. They may be two or three times as large as a polynuclear cell and have a large irregular cytoplasm and sometimes an irregular nucleus.

Prolapse of the Gravid Uterus.—By P. Findley. (See MEDICAL RECORD, Vol. 80, page 105.)

Syphilis and Parasyphilis of the Nervous System.—E. D. Fisher points out the differences between tabes and paresis, as well as their resemblances. Some authorities, like Mott and Ferrin, consider the two diseases the same, the differences only depending on their situation. The author combats this opinion. No case of paresis runs its course without spinal involvement, but nowhere is it as complete as in tabes. The cranial nerve lesions are different, the sensory symptoms predominate in tabes, and the shorter duration of paresis is another important point. Syphilis of the nervous system differs etiologically, clinically, and pathologically from the parasyphilitic diseases.

Phenol Injection Treatment of Sphenopalatine Neuralgia.—G. Sluder states that alcohol injections, such as are used satisfactorily on the nerve trunk, have not given satisfaction in the severe form of sphenopalatine neuralgia described by him in 1907. They have given relief for short periods of time only and always cause considerable pain which may last for several days. For the lesser grades of this neuralgia the alcohol injections have proved curative. The author has found in the severer forms that 5 per cent. phenol in alcohol injected into the sphenopalatine ganglion to the amount approximately of one drop is painless and apparently curative for the various forms of neuralgia. In this method cocaine is first caused to soak into the ganglion from the mucous membrane covering the sphenopalatine forearm. A straight needle is then introduced from in front backward and upward under the posterior tip of the middle turbinate, a distance of 5 to 6 mm.

Imperforate Anus.—C. H. Hamilton reports a case of this condition in a male infant, associated with an undeveloped colon which was 1 cm. in diameter and constricted at intervals of 8 cm. throughout its entire course.

The Lancet.

December 23, 1911.

Some Points in Heredity.—R. Clement Lucas criticises the doctrine of diathetic inheritance as applied to such diseases as gout, tuberculosis, syphilis, leprosy, malaria, and cancer. Syphilis, he believes, is not an hereditary disease. The microorganism causing it is transmitted through the mother to her child when the placental protection breaks down. In the field of eugenics the author suggests a practicable mode of sterilizing criminals and others with the *x*-rays. Twin bearing is hereditary. The Mendelian doctrine fails when applied to the cross-breeding of human races. When a negro unites with a white the result is a half-caste or mulatto. So also when a European unites with an Indian the result is a Eurasian. Mulattoes united in marriage should, according to the Mendelian law, segregate out into pure blacks, pure whites, and intermediates, but they do not; they continue to produce mulattoes, and Eurasians continue to produce Eurasians. Numerous pedigrees show the tenacity with which a defect or deformity, once developed, clings to a stock and is repeated generation after generation in spite of the infusion of new blood.

Ionic Treatment in Gynecology.—S. Sloan discusses the physics and chemistry of ionic medication and describes the apparatus required. The object of ionic treatment in gynecology is to remove sepsis and the accompanying inflammatory exudations. In inflammation of the tubes, ovaries, or the cellular tissue, if no suppuration is present, the iodine ion gives the best results. If the case is one of simple cervicitis then the zinc or copper electrode, covered with cotton wool, is inserted into the cavity of the cervix through the speculum, which is filled with a 1 per cent solution of the bichloride of the metal employed. When the endometrium is involved the zinc electrode should be introduced into the uterine cavity and if insufficient action results or the case is a very chronic one the copper electrode must be used. The latter is more likely to cause pain and bleeding. In cases of prolonged uterine hemorrhage the copper is the more potent electrode, although where the patient is very sensitive or there is any reason to fear pelvic cellulitis it is well to avoid the use of the bare copper electrode. Either the zinc or the copper can be used with perfect safety in solution by means of the speculum in all cases of sepsis of the cervix. Before an electrode is introduced into the cavity of the uterus, however, the vagina and the cervix must have been rendered as far as possible aseptic by ionic treatment if necessary, after which with moderate care no harm can result from the intrauterine application.

Ruptured Esophagus.—D. W. Roy reports a case of this condition associated with fat embolism in a man aged forty-three years who succumbed after an amputation of the leg for compound fracture. The author believed that the rupture of the esophagus resulted from the violent straining manifested by the patient during anesthesia.

Induration of Mediastinum.—W. Branden and J. B. H. Holroyd report a case of extensive fibroid induration of the mediastinum and right lung, with ulceration and sclerosis of the right bronchus, as well as perforation of the pulmonary artery of the same side. The disease occurred in a man aged sixty-two years. The case presented unusual difficulties in diagnosis and probably belonged to the class of pulmonary syphilis.

Carcinoma of the Colon.—J. S. Manson reports two cases which seem to be of special interest in showing that carcinoma of the lower bowel may coexist with various forms of benign growths of the female pelvic organs, and that the prominence of the latter may mask almost entirely the graver disease which gives so little sign of its presence.

Nervous Vomiting in Childhood.—E. B. Smith reports a series of seven cases presenting a type of nervous vomiting occurring in children about the age of the second dentition. The evidence in favor of the condition being a purely functional one is: (1) The underlying current of nervous instability or nervous inheritance present in every case. (2) The fact that the vomiting in at least the first two cases was preceded, accompanied, or followed by other functional nervous disorders, *e.g.* migraine and enuresis in the first case and habit spasm in the second, while the third case was a rheumatic subject and the seventh case suffered from the common precursor of functional nervous disorders, namely, rickets. The effects of unsuitable environment were demonstrable in the fifth case.

Ectopic Gestation.—W. M. Fergusson reports two cases of this condition with primary rupture into the abdominal cavity.

Appendicitis in a Scrotal Hernia.—C. H. James reports the case of a boy seven years old who had several attacks of appendicitis with an appendix situated in the sac of a scrotal hernia. There were three distinct and typical attacks of appendicitis, the last of which resulted in an abscess of the scrotum which opened externally and formed a permanent sinus. The track of the sinus was the lumen of the proximal portion of the appendix. In spite of this no fecal matter ever escaped by this route. Operation was followed by recovery.

Medical Education and Examinations.—J. Griffiths believes that medical boards should throw upon the medical schools the responsibility of training and certifying the medical student as a fit and proper person to enter a hospital for training in clinical work; the machinery for giving such training should be under the inspection and supervision of the boards. The clinical training should extend over a period of three years, and each student should be examined in the work done at the end of every complete course. The certificates for each course should form the record of the student, and as soon as all certificates are duly filled the student should be entitled to State registration and to all the privileges such protection affords.

Abdominal Section Under Spinal Analgesia.—L. McGavin reports a series of sixty-five cases of laparotomy in which spinal analgesia was employed. The results in these cases were sufficiently encouraging to warrant the employment of this method more frequently in abdominal surgery, combined when necessary with general anesthesia. It may be found possible to replace this general anesthesia by injections of scopolamine and morphine and so to overcome the hypersensitiveness of the peritoneum and [illegible] malignancy.

Spinal Anesthesia.—O. Richards presents a study of 500 consecutive cases in which spinal anesthesia was employed. He concludes that this method, owing to its limited field, can never replace general anesthesia. Yet in a number of cases spinal anesthesia offers advantages which cannot be got in any other way, and its apparatus and technique are so simple that it is worth any surgeon's while to use it whenever there is anything definite to be gained by it. In the large number of cases in which there is nothing to choose between the methods the use of stovaine becomes a matter of taste and convenience. There seems to be a tendency in England to regard spinal anesthesia as a dangerous method and one that can only be employed successfully by a few experts who have devoted their attention to it. As far as the author's experience goes this is less true than it is of chloroform—the danger of spinal anesthesia is about the same, and the skill required for its administration is less.

Paroxysmal Tachycardia.—R. O. Moon reports a case of this condition.

Leucodermia Undergoing Pigmentation.—K. H. Jones reports a case of leucodermia in which exposure to the sun caused pigmentation in the areas affected.

Berliner klinische Wochenschrift.

December 11 and 18, 1911.

New Form of Hernia.—Pochhammer describes a case under the designation "properitoneal abdominal hernia in an old abdominal scar, strangulation of the hernia, intestinal gangrene, resection." The scar was due to laparotomy for rupture of the uterus intrapartum, and the hernia occurred two years later. It was readily replaced and an abdominal bandage worn. After three years of the hernia the latter became irreducible and the picture of strangulation appeared. The gut ruptured during the operation and 150 c.cm. had to be resected, for there were two loops in the hernial ring, which was seated in the posterior sheath of the rectus. Recovery was smooth.

A "Scalped" Finger.—Katz describes and illustrates a case of complete flaying of the left middle finger, which occurred to a woman as a result of falling from a ladder, which she was grasping at the time with her left hand, while holding a basket of laundry in the other hand. The fall was due to a faint. The rationale of the injury remained a mystery. Patient wore no ring and there was no nail or splinter in the rung of the ladder. She doubtless made a powerful instinctive effort to save herself, but this effort was antagonized by the force of gravity. The patient was not seen until some time later, and the detached skin was not recovered. The denuded finger was covered with flaps from the skin of the chest.

Progress in Knowledge of Tropical Diseases.—Hoffmann states that after a brilliant era of discoveries in this field a period of relative barrenness has succeeded, and proceeds to indicate some few things which have come to light quite recently. Incidentally he remarks that a period of amplification of older discoveries, of organization which shall apply the same, of new reference books, journals, societies, laboratories, etc., has necessarily followed upon the era of sensational discoveries. The recent epidemic of the plague in Siberia has caused us to modify our views of this affection. Rats and fleas play no part whatever in the spread of the pneumonic form of plague, while they are practically the sole etiological factor in the spread of the bubonic form. Not all species of rat flea propagate the disease; two only are so concerned, and alone need to be watched for. Cyanogen will destroy the flea but has no power over the bacilli. The use of iodoform is recommended as a preventive against the visitation of the flea. In the field of cholera the technique for cultivating the vibriones has been much advanced by various procedures, and older resources have been pronounced untrustworthy. The problem of fighting cholera consists in measures

directed wholly against the germ carriers. While leprosy germs may not be cultivated and made to reproduce the disease in animals, we are still in ignorance as to the natural mode of diffusion. If it could be shown that insects, especially the bed-bug, actually transmit the disease, this view would harmonize well with all the known facts, although direct transmission would by no means be excluded. That beriberi is due to phosphorus starvation seems to have been crucially demonstrated. The phaseolus bean when added to the diet seems sufficient to prevent the disease. The latter seems very prone to develop in the wake of acute infectious diseases, and may not itself constitute an affection *sui generis*. The part played by body lice in spreading exanthematous typhus is now recognized and taken into account in the prophylaxis. No advance has been made in identifying the bacterial cause. For the present the tabardillo or Mexican typhus must be regarded as identical with typhus proper. The papataci fly has recently been discovered in South America, although it has hitherto been believed to be a denizen of the old world only. The subject is not exhausted in the present issue and the article will be continued.

Treatment of Pulmonary Tuberculosis with Formation of Artificial Pneumothorax.—Klemperer sums up his article on this subject as follows. The establishment and maintenance of an artificial pneumothorax is an undertaking of some magnitude, but when properly carried out is not especially severe or dangerous. It can never be considered in connection with early or mild cases, but need not be restricted to the most severe cases. Whenever the dietetic-physical treatment, and the sanatorium and climatic cures and the application of tuberculin have all failed to control the disease, which advances even if ever so slowly, we should think of the possibility of the artificial pneumothorax before it shall be too late. Experience with cases in which a permanent pleural exudate is replaced by gas, and with others in which hemoptysis has furnished the indication, has shown that the best results are to be expected in a somewhat early stage, with symptoms of moderate severity.

Ultimate Results of Surgical Intervention in Graves' Disease.—Coenen analyzes some material recently reported by different operators. Baruch controlled 90 cases for a period of eighteen years, of which 51 had been treated by operation. Eighty of the patients he saw personally. Of those treated conservatively 18 per cent. had died, while under surgical treatment the mortality was 15.8 per cent. Of the 51 patients treated by operation not one had died of Graves' disease. The percentage of operative cures was 37.5; of improvements, 35.5; while 15 per cent. were not improved. Of the cases treated conservatively not one was completely cured and but two were essentially benefited. After operation the cases with cardiac hypertrophy became normal in this respect in 70 per cent. The amount of benefit derived from the operation appeared to be in direct proportion to the amount of parenchyma removed. Generally speaking there is a universal tendency of all symptoms of Graves' disease to improve after operation. This is seen notably in the exophthalmos. The work of the Kochers and of several other heavy operators appears to bear out the trustworthiness of Baruch's reports.

Varicose Veins.—Unger reviews some of the recent literature of this subject. Berger has lately compiled a bibliography of the latter which comprises 1,000 titles. The conclusions based on an analysis of this immense material are few in number. All young people should be operated upon as soon as the varices become an impediment to their activities. The earlier an operation is performed the better. The least dangerous and most satisfactory method is extirpation of the diseased portions of the veins. If the varices are extensive the entire saphenous vein, from the fossa ovalis to the ankle, should be resected. The vein should always be ligated and resected at its mouth. The operation is contraindicated, the author maintains, in patients of advanced age and in those suffering from any severe general disease.

Münchener medizinische Wochenschrift.

December 5, 1911.

Hernia of the Umbilical Cord.—Hannes states that children almost invariably perish as a result of this malformation. The latter is of rare occurrence, six cases having been seen in Küstner's clinic since 1900. Death usually occurs during the first week from peritonitis. The author therefore attempted to save the patient by a radical operation. The condition was recognized ten hours after delivery. The stump of the cord had become transformed into a tumor the size of a goose egg. At the insertion was a small defect of skin, through which the cranium was visible. Beneath the latter lay the intestine. The tissues down to the peritoneum were dissected off and the latter cautiously incised and extirpated in the area of the rupture. The hernial ring was enlarged, the intestines replaced, and the opening well sutured. Convalescence was smooth. Of the six cases alluded to this makes the fifth to be operated on successfully. One was left without intervention and died on the eighth day with an intestinal fistula. The children operated upon did not all survive, but death could not be attributed to the operation alone, and in one case at least of two which ended in death the operation could not be accused at all. One child died of asphyxia, to which the operation doubtless contributed. In summing up the results, Hannes states that at least four lives were saved for the time, and three of the children are still living.

Anesthesia in Normal Labor.—Weinmann discusses the use of anesthetics in physiological labors. Here belongs the inhalation of a few drops of chloroform or ether at each pain during the expulsive period. The author believes this practice to be very common in England and the United States, but states that it has not much vogue in Germany. Many routine practitioners inject morphine during the period of dilatation. It is said not to interfere with the latter, but caution is urged against using it too soon. Lumbar anesthesia may be used in selected cases. In nearly all maternities the morphine-scopolamine narcosis has been thoroughly tested. While some regard it as an ideal procedure, others have accumulated a long series of collateral effects and sequelæ which tend to bring discredit upon it. The author prefers pantopon alone as a routine measure, combined with scopolamine, if the pain is unusually severe.

Salvarsan in Scorbutus.—Since much of the picture of buccal scurvy is due to the activation of the mouth spirochetes, Tuschinsky and Iwaschenzow have tested the action of salvarsan, which has already been shown to destroy these parasites in various kinds of stomatitis. The bad state of nutrition in these patients is due largely to the condition of the gums. Repeated small doses of the drug caused a notable reduction in the number of spirochetes with corresponding improvement.

Motor Aphasia from Subdural Hematoma Cured by Trephining.—Borchers adds a case to the six successful operations which he found already recorded. The bullet which caused the hematoma did no further damage, while the compression of the brain substance left the latter quite intact. There were compressed the third frontal convolution (left side) and part of the central convolution, so that there was complete failure of the cortical functions pertaining to this locality. The functions returned at once and completely as soon as the pressure was removed.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

PERSONAL HISTORY.

Syphilis.—Ascertain the date of initial lesion, the nature and approximate date of the secondary symptoms, the occurrence of any tertiary indications, the date of the last manifestation of the disease and of last treatment. In order that the medical officers at the home office may get a true picture of the early conditions, they will sometimes express the desire to have the applicant requested to furnish a statement from the only one in a position to give the information with authority—the attending physician.

While insurance offices have somewhat different methods of dealing with this question, they are practically unanimous in their conclusions that syphilitic infection is a distinct prejudice to a proposer for insurance. In other words, if insurable at all, the person who has been subject to syphilis is not eligible to insurance at ordinary rates, but most companies will issue an endowment or a rated up policy if they have good evidence that the applicant took adequate treatment, that the disease was arrested in the secondary stage, and that a period of time, varying from three to five years, according to the conviction of the company interested, has elapsed since the last manifestation of the disease and the cessation of treatment. The free use of alcohol increases the hazard of these risks.

Many cases have been observed by various authorities in which late constitutional symptoms followed what was supposed to be thorough early treatment. It must, therefore, be assumed that a large percentage of syphilitics will not live out their expectancy. The two chief elements in causing loss in this class of proposers are vascular changes, especially of the arteries of the brain and heart, and diseases of the nervous system in the form of general paralysis of the insane and tabes dorsalis. Most of the deaths from cerebral apoplexy, cerebral softening, sclerosis of the coronary arteries, and localized or general arteriosclerosis occurring before the age of fifty or fifty-five may justifiably be regarded as due to syphilis.

The issuance of an endowment policy that will mature between the ages of fifty to fifty-five, or of a policy rated up so that the premium will be large enough to protect the company against excessive loss in insuring these applicants as a class if they die at the ages stated, is the only practice that may be pursued safely in assuming these risks.

Before leaving this subject the examiner should be warned that some applicants will practise deception when questioned in regard to this subject. The acknowledgment of any venereal sore should lead to a careful investigation and all the facts reported even if the examiner is convinced that the lesion was a simple ulcer or chancroid. It may be expedient to omit the history of a venereal disease from the report, as many applicants will object to having it written in the examination blank where it will be seen by other persons. In that case, the full information may be sent in a separate communication or confidential letter directly to the home office, but the examiner should mail it *at once* and in a carefully addressed envelope.

Abscess, Ulcer.—Give date, duration, nature, part affected, and recurrences if any. A full account of any surgical interference and pathological findings should accompany the report. The object of chief interest in these cases lies in the fact as to whether or not there was any suspicion of diabetes, syphilis, tuberculosis, or malignancy, and it may be necessary to have the applicant furnish a statement from the physician who had the opportunity of observing the condition at the time of its occurrence before doubt can be removed.

Tumor.—Give the date, duration, nature, size, location, part involved, recurrence, and increase in size, if any, during the past two or three years. The examiner should always endeavor to secure a report of any pathological findings and surgical assistance. In these cases, also, it may be necessary to resort to a certificate from the attending physician or operating surgeon in order to clear up any suspicion of malignancy, tuberculosis or syphilis.

Diseases of the Skin.—Give dates, duration, extent, nature, parts involved, and number of attacks. The examiner will be expected to inquire closely into the nature of any skin trouble in order that he may determine whether it was a syphilide, tuberculide, or of a malignant character. It may not be possible to clear up the matter satisfactorily until the attending physician is communicated with. When the disorder was of a benign nature, such as eczema or psoriasis, it is important to know the extent and location of the surface of the body involved, and when it still exists covering large areas, such as the entire trunk, or has recurred often, it is apt to be a sign of some dyscrasia or constitutional disturbance and possibly call for rejection or the issuance of an endowment policy.

Disease of the Nose.—The ordinary and simple catarrhal troubles, so prevalent, need not excite any comment, but there should be some inquiry as to whether the catarrh is of a more serious nature, whether there is any condition requiring surgical interference such as extensive malformations of the bony structures or polypi. If there is a history of polypi with removal, it is advisable to ascertain the number of recurrences, if any, and the date of the last operation, as from six to twelve months should elapse in these cases, according to the number of removals, before acceptance of the risk.

Diseases of the Ear.—The chief trouble in the ear in which the life insurance companies are interested is otorrhea, some being considerably more exacting than others. There has been some relaxation in regard to the matter and it may be stated in a general way that these subjects may be insured when the discharge is neither bloody nor offensive, when it is not associated with pain or tenderness, when no granulations, polypi, or carious bone are present, and when the perforation is in the anterior lower segment of the drum, thus insuring good drainage. Most of these data can only be furnished after an examination of the ear has been made, and as the cases as a whole are not good risks, a statement from a competent aurist should be insisted upon before issuing a policy. Some companies do not accept such risks until at least two years have elapsed since the last appearance of any discharge. Extension of the inflammation to the tissues about the brain is not the only menace in otorrhea, as there is a fairly marked tendency to tuberculosis in those subject to it.

Scrofula, Swelling or Suppuration of the Glands.—In most subjects with either one of these troubles, the condition is due to tuberculosis or a tendency to

it, although it may arise from syphilis or lukemia. The examiner should, therefore, investigate carefully into the personal history and obtain, whenever possible, a report of any pathological examination.

Surgical Operations.—Give the date, diagnosis of the condition for which the operation was done, nature of the operation, the structures involved, the end result, any remaining effects, and state whether there was any suspicion of malignancy. It is often necessary to have the operating surgeon furnish a certificate covering these facts as well as any pathological findings, and whether there was any suspicion of malignancy or tuberculosis.

Deformities or Loss of Limbs.—When there has been an amputation of an arm or a leg, give the point at which the operation was done, especially when at shoulder or hip joint as this constitutes an impairment in most cases. The condition of the stump should be looked into, and it should be stated whether or not the applicant uses crutches when the lower extremity or a part of it has been removed.

In hip joint disease, try to find out if the original trouble was tubercular in character, and note carefully the presence of any scars in the region of the joint.

In spinal curvature, it is essential to know whether the curvature is lateral or anteroposterior, as the latter usually indicates former tuberculous disease. When the curvature is lateral, give some idea as to the amount of deformity and the amount of deviation by actual measurement from the median line, as many of these cases are acceptable if the deformity is not too great.

Hernia.—When there is a hernia, ascertain if there has ever been any difficulty in reducing it or in maintaining it by means of truss.

The National Sickness and Accident Insurance Law of Hungary.—Sir Thomas Oliver writes at some length on the national sickness and accident insurance law of Hungary, having investigated the matter during visits paid to Hungary during the past seven years. In Hungary there is no invalidity insurance, no insurance for unemployment, nor is there an old age pension. Insurance for sick benefit is obligatory on all employees in every branch of trade and commerce whose salary does not exceed $500 a year or $1.75 a day. The full income from all sources must not exceed $500 a year. On the other hand, insurance against accident is obligatory in every dangerous trade scheduled in the Act, quite apart from any relation to the amount of salary received by the individual; but for the purpose of recompense no salary is taken into consideration as being more than $500 a year, that is payments are only made upon that amount.

Sick benefit and accident insurance are united in and controlled by one central fund, upon the adminstrative body of which employers and employees are equally represented. In the event of disagreement, questions are referred to a selected jury. Since insurance against accident is not compulsory for workmen employed in some of tht less dangerous trades, and is not compulsory for persons employed in commerce, the scope of the insurance fund is the wider of the two. Under sick benefit are included: medical and surgical attendance, medicine, sanatorium and hydropathic treatment, and provision for personal maintenance; this provision is one-half of the wages of the individual insured, but in certain circumstances it may be raised to two-thirds of the wages. The financial allowance may continue for twenty weeks, and as it can be extended for one year, it takes the place to some extent of an invalidity fund. Malingering is far from uncommon. Maternity benefit is allowed for six weeks, but should recovery be retarded the benefit can be extended to twenty weeks.

In the event of an accident the sickness fund pays all expenses to the insured person for the first ten weeks; after that payments are made from the accident insurance fund. There is no liability over $500. Should there be complete incapacity for work the insured person receives 60 per cent. of the $500, but in the event of extreme indigence this may be increased to the full 100 per cent. Should an injured workman be taken to a hospital, the hospital receives 60 cents a day for thirty days, but this can be extended. A member's sick child can also receive medical attendance or hospital treatment free of charge for thirty days. As payment for injuries is made for the first ten weeks from the sickness instead of the accident insurance fund, a considerable strain is thrown upon the sickness fund; this is inequitable, since, owing to the effects of many of the accidents not lasting so long as ten weeks, the burden of maintenance falls upon the sickness insurance fund, to which employers and employees equally contribute, while the accident insurance fund, supported entirely by the employers, escapes. Syphilis, insanity, and trachoma are not paid for by the national insurance fund, but in a special manner by the State. In the event of death following an accident, funeral aid is given to the extent of twenty times the daily wages; the widow receives a pension equal to 20 per cent. of the yearly wages; each child receives 15 per cent., which is doubled in the event of the mother being dead; parents, grandparents, and orphan grandchildren receive 20 per cent. of the wages so long as the total sum of all the payments does not exceed 60 per cent. of the yearly wages of the injured workman. The State, it will be observed, makes no contribution in money to the sickness or accident insurance fund. It provides the buildings, the State workmen's insurance offices, and bears the expenses of administration. For the purpose of the Act, Budapest and the provinces are divided into districts. There are ninety-six district insurance offices. Each office has its own special medical institution. In the Budapest district there are 230,000 persons insured against sickness and 200,000 against accidents. The income for last year was $250,000. Of the 20 per cent of the income set aside for medical purposes, 15 per cent. goes to pay certain fixed sums to the medical men for outdoor patient work. The remaining 5 per cent. of the 20 per cent. is set aside for medical expenses incurred by visits made to the houses of the sick.

There are six medical institutions in Budapest where consultations are given daily, except on Sundays, by specialists. They are paid out of the 15 per cent. received from the total income of the fund. They receive in addition to a fixed salary a further amount according to the number of patients they examine. To the medical institutions attached to the insurance funds in Budapest all persons who are insured against sickness and accident can resort for special medical and surgical advice. These medical institutions, or ambulatoria, resemble the out-patient departments of our large hospitals. There are five medical institutions of a similar character in Budapest. Sir Thomas Oliver also discusses the working of the fund in provincial districts. On the whole the National Sickness and Accident Insurance Fund seems to work well in Hungary. —*British Medical Journal*, Aug. 19, 1911.

Life Insurance Payments.—During the year 1910 over 500 million dollars was paid out in claims and benefits by the life insurance companies and benefit associations in the United States and Canada. During the same year new insurance to the amount of more than 2,500 million dollars was written, the total insurance in force showing an increase of nearly 1,000 million over the year 1909.

Book Reviews.

PAIN: Its Causation and Diagnostic Significance in Internal Diseases. By Dr. RUDOLPH SCHMIDT, Physician to the Royal Empress Elizabeth Hospital, Vienna. Translated and edited from the Second Enlarged and Revised German Edition by KARL M. VOGEL, M.D., Assistant Professor of Clinical Pathology, College of Physicians and Surgeons, Columbia University; Clinical Pathologist and Assistant Attending Physician, St. Luke's Hospital; and HANS ZINSSER, A.M., M.D., Professor of Bacteriology, Leland Stanford, Jr., University. Second Edition. Price $3.00. Philadelphia and London: J. B. Lippincott Company, 1911.

PAIN is the most common and most important symptom which challenges the diagnostic and therapeutic skill of the practitioner. There are few diseases in which pain does not at some stage play an important rôle. In his eagerness to relieve this symptom the physician has been apt too often to overlook its significance as a signal of disease, either organic or functional. The well-known work of Rudolph Schmidt, which was introduced to English readers three years ago, now appears in a second and revised edition. In this, as in the former edition, the translators and editors have executed their task with consummate skill. Among the new features of the second edition may be mentioned the introduction of short case histories bearing on the topics under discussion and the more elaborate consideration of headache and gastralgia. An idea of the scope of this work may be conveyed by the citation of the chapter headings, as follows: the sensation of pain; the functional modification of pain; topography in its relation to pain; quality and time of occurrence; the nervous system; organs of motion; digestive system; urinary system and spleen; respiratory and circulatory systems; and cutaneous tenderness in visceral disease. The last chapter, which is devoted to a presentation of Head's researches on referred pains, has been added by the editors. It contains also an excellent series of diagrams showing the commoner seats of pain or tenderness in visceral disease. As one reads this volume one is profoundly impressed with its eminently practical character. It is the product of the hospital ward, the sick room, the clinic, the consultation room, and the pathological laboratory. The author draws upon his vast experience, and not upon that of others, as embodied in the literature. It is this refreshing originality which has become a rare commodity in these days of countless publications that, more than anything else, characterizes Dr. Schmidt's splendid volume.

A STATISTICAL SURVEY OF INFANT MORTALITY'S URGENT CALL FOR ACTION. By EDWARD BUNNELL PHELPS, M.A., F.S.S.; Editor *The American Underwriter* of New York City; Author of "A Statistical Study of Infant Mortality," "American Mortality Statistics," etc.

THIS is an address delivered at the first annual meeting of the American Association for Study and Prevention of Infant Mortality, at Baltimore, November 9-11, 1911, and is reprinted from the Transactions of the Association. The author presents a careful statistical study showing that throughout the world there is a mortality rate of at least 13 deaths under one year for every 100 living births. The fact is emphasized that probably two or three times as many infants manage to survive the adverse conditions to which they are subjected, but nevertheless retain the blighting effects of the latter throughout life.

THE INDIVIDUALIZATION OF PUNISHMENT. By RAYMOND SALEILLES, Professor of Comparative Law in the University of Paris and in the College of Social Science. With an Introduction by GABRIEL TARDE, Late Magistrate in Picardy and Professor of Philosophy in the College of France. Translated from the second French edition by RACHEL SZOLD JASTROW. With an Introduction by ROSCOE POUND, Professor of Law in Harvard University. Price $4.50. Boston: Little, Brown & Company, 1911.

THIS is the fourth volume in the series of books on modern criminal science published under the auspices of the American Institute of Criminal Law and Criminology. It is a profound study of a subject that concerns the jurist more than the physician; nevertheless, the alienist who is called upon to testify in a criminal case will profit by a careful perusal of this book, the greater part of which deals with the doctrine of responsibility in its various aspects in relation to crime. The titles of the chapters are as follows: the statement of the problem; the history of punishment; the classic school; the neo-classic school and individualization based upon responsibility; the Italian school and individualization based upon formidability; the doctrine of responsibility; responsibility and individualization; legal individualization; judicial individualization; and administrative individualization. The subject matter of this book touches the most abstruse problems in philosophy, such as that of free will versus determinism. The doctrine of responsibility from the viewpoints of psychology, medicine, sociology, law, penology, etc., is carefully unfolded. Although difficult reading, the text reveals the skill of the translator, who has rendered the meaning of the author into lucid and elegant diction.

CLINICAL AND MICROSCOPICAL DIAGNOSIS. By FRANCIS CARTER WOOD, M.D., Professor of Clinical Pathology, College of Physicians and Surgeons, Columbia University, New York; Director of the Laboratories and Attending Physician to St. Luke's Hospital, New York. Third Edition. With 194 illustrations in the text and nine colored plates. Price $5.00. New York and London: D. Appleton & Company, 1911.

THE appearance of three editions of this work within a period of six years testifies to the commendation with which it has been received. A profound grasp of the subject of clinical pathology together with a didactic skill and facility of expression has enabled the author to present a work that is admirably suited to the needs of the student and general practitioner. The subject matter of the present edition includes descriptions of the latest developments of the art of laboratory diagnosis. The technique of the Wassermann reaction and the preparation of vaccines are described in full. Sulphemoglobinemia, the antiformin method of examining sputum for tubercle bacilli, the tests for trypsin and erepsin in the feces, the tuberculin tests, the diagnosis of hydrophobia by means of smears from the brain, Folin's analytical methods in the examination of the urine, Herter's study of putrefactive processes by means of urinary analysis, the determination of arsenic in the urine, and hemolytic tests on the blood are among the subjects that have been introduced into the present edition. There is, however, no mention made of the glycyltryptophan test, of the cobra-venom reaction, of the phenolsulphonephthalein test. These may, however, be intentional omissions or they may have been too recent to permit their inclusion in this work. The latter is singularly free from error, is well written, and embellished with many fine plates and illustrations. The typography, paper, and binding are in keeping with the character of the text.

TUBERCULOUS DISEASES OF BONES AND JOINTS. Their Pathology, Symptoms, and Treatment. By Sir W. WATSON CHEYNE, Bart., C.B., F.R.S., F.R.C.S., D.Sc., etc.; Professor of Clinical Surgery at King's College Hospital; Senior Surgeon to King's College Hospital; Consulting Surgeon to Paddington Green Children's Hospital, etc. Price $5.50. London: Henry Frowde, Oxford University Press; Hodder & Houghton, 1911.

IN this well-printed and handsomely illustrated volume of 404 pages the author presents the second edition of his well-known work. The justification for a new edition is seen in the many modern developments in the treatment of tuberculous diseases of the bones and joints, which developments have proceeded along the lines of conservative rather than of operative treatment. The first half of the book is devoted to the consideration of bone and joint tuberculosis in general, its history, pathology, and treatment, while the second half takes up in turn the different joints and discusses them in detail. The entire subject is presented in a most thorough manner by one who is entitled to speak with authority on this important group of surgical affections.

DIE ERKENNUNG DER PSYCHOPATHISCHEN KONSTITUTIONEN (krankhaften seelischen Veranlagungen) UND DIE ÖFFENTLICHE FÜRSORGE FÜR PSYCHOPATHISCH VERANLAGTE KINDER. Von Prof. Dr. TH. ZIEHEN, Geh. Med.-Rat, Direktor der Psychiatrischen und Nervenklinik der Kgl. Charité in Berlin. Price .80 mark. Berlin: Verlag von S. Karger, 1911.

THE distinguished director of the psychiatric and neurological clinic of the Charité discusses in this essay that large group of children who exhibit no distinct disease of the mind, who are not at any rate victims of idiocy, imbecility, or debility, but who show to a greater or lesser degree numerous manifestations of disorders in the affective sphere of the mind. These disorders lead to antisocial tendencies, such as crime, vagrancy, and prostitution. These conditions are comprised under the term "psychopathic constitutions." The author discusses the means of recognizing these states and the public institutions established for the care of children affected with them.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Twenty-Fourth Annual Meeting, Held in Washington, D. C., December 12, 13, and 14, 1911.

THE PRESIDENT, DR RUDOLPH MATAS, OF NEW ORLEANS, LA., IN THE CHAIR.

The Effect of Ligation of the Ureters.—DR. LOUIS FRANK of Louisville detailed a series of experiments concerning ligation of the ureters in animals. In many instances the ligation was followed by primary hydronephrosis. He exhibited specimens showing definite changes that took place in the kidneys after ligation of the ureters. Atrophy, without much change in the kidney, occurred in from 80 per cent. to 90 per cent. of the cases in which the ureters were ligated. Ligation of the ureter in operating was not an accident that was to be absolutely disregarded, as it left behind unpleasant conditions.

Dr. ALBERT VANDER VEER of Albany recalled the case of a patient who suffered decided pain for six years after an operation. The right ureter was accidentally ligated with silk. The patient came to him at the end of this time for relief. He made an exploration and found a sacculated condition of the left kidney, in which there were a number of abscesses. This kidney was removed and the patient recovered. The ligation of the ureter at the previous operation resulted in a train of symptoms, which went on for six years until relief was afforded by the removal of the left kidney.

Dr. ROBERT T. MORRIS of New York stated that the ureter had often been accidentally ligated by the surgeon in doing pelvic work when he did not know that he had done so, and the patient had never found it out because it gave rise to no symptoms. One should strive to guard against this accident in one's surgical work.

Dr. J. WESLEY BOVEE of Washington, D. C., was quite in accord with Dr. Frank that it was safe to ligate the ureter that was passing normal urine up to the limit of six weeks, and if one removed the ligature any time within that six weeks the function of the kidney was resumed and it would continue. But beyond that time, so far as experimentation was concerned, the function of the kidney was totally ended.

Dr. H. A. ROYSTER of Raleigh, N. C., agreed with Dr Frank that ligation of the ureter during operation was a more serious matter than we had been heretofore willing to admit, and sometimes a patient died following this accident.

Dr. GUY LEROY HUNNER of Baltimore firmly believed that ureters were tied without our knowing it. He had tied, to his knowledge, three ureters during operations. Both ureters were tied in one patient, and in the other the ureter was tied in a patient suffering from a condition similar to that of the first one, namely, cancer of the cervix.

Dr. RICHARD A. BARR of Nashville said that if a surgeon should tie both ureters he should undo his work and try to save the patient's life. In many cases we were confronted with the necessity of removing a kidney or implanting the ureter into the bowel, and where we were sure the patient had another kidney the simplest method was to tie the ureter off and remove the kidney at a subsequent operation.

Dr. FELIX E. BALBRIDGE of Huntsville, Ala., did not think the impression should go out from the association that there was no danger attending the ligation of these ureters. His experience had been unsatisfactory in that regard. He recalled one case in which he accidentally tied the ureter while operating, and the patient died five days afterwards.

Cancer of the Rectum and Lower Sigmoid with the Report of a Unique Case.—DR. MILES F. PORTER of Fort Wayne, Ind., said that every rectal neoplasm should be regarded as malignant until it was proven to be innocent. Cancer of the rectum or sigmoid rarely, if ever, developed from ulcer, fistula, or stricture. It was important to remember that cancers in this region were peculiarly prone to infection. Not infrequently nonmalignant tumors were removed under the impression that they were malignant conditions which subsequent events proved to be nonomalignant. December 12, 1907, he operated at Hope Hospital on Mrs. Y., who was referred to him by Dr. Ely of Plymouth, Ind. The patient had been having fecal vomiting for forty-eight hours when she was admitted. On opening the abdomen there was found what was taken to be an inoperable carcinoma of the lower sigmoid. The gut was divided well above the lesion, the lower segment closed and dropped, and the upper end anchored in the wound, establishing an inguinal anus. The patient was discharged from the hospital nineteen days after the operation. Some months later he saw the patient at her home. She seemed to be in good health, but was anxious to have the artificial anus closed. He explained to her why this could not, or should not, be done. The artificial anus at this time seemed quite small, due to cicatricial contraction. Later this contraction increased until it became very difficult for the bowel to empty itself, and the patient suffered severely at times on this account. During one of these attacks of pain there occurred a stool via the natural anus, which was followed by relief. Shortly after this Dr. Ely wrote him that the artificial anus had completely closed and the patient was well. The practical lessons which this case and others taught were: (1) That operative relief should be offered to all patients supposed to be suffering with cancer of the rectum and sigmoid, no matter how desperate they seemed. (2) That radical operations should not be undertaken except upon positive microscopic evidence

Umbilical Tumors Containing Uterine Mucosa or Remnants of Müller's Duct.—DR. THOMAS S. CULLEN of Baltimore referred to a case of intestinal polyp at the umbilicus and showed a photograph of the umbilicus with a small irregular tumor projecting from the umbilical depression. In the lower power picture it was possible to see the outer surface of this polyp covered by typical intestinal mucosa, and with the high power the junction of the squamous epithelium and intestinal mucosa. This polyp was very clearly seen. It was one of those cases in which the outer end of the omphalo-mesenteric duct had remained open. This patent extremity had turned inside out, presenting a polyp with intestinal mucosa on its surface. He then considered from the literature several cases in which umbilical tumors contained glands of an unusual type. After discussing the subject at length, he gave the following epitome of the composite picture of these tumors: at some time between thirty and fifty-five years a small tumor developed at the umbilicus, reaching its full size in the course of a few months. It was usually described as being the size of a small nut. Sometimes it was painful, especially at the menstrual period, and in at least one instance there was a brownish yellowish discharge from the umbilicus at such times.

The overlying skin was usually pigmented and there might be one or two bluish and brownish cysts just beneath the surface. These might rupture and discharge a little brownish fluid, and old clots. On section the nodule was dense, and was traversed by glistening dense fibrous tissue. Scattered throughout the nodule one sometimes found small spaces presenting a sieve-like appearance. These spaces were filled with brownish fluid. Occasionally there might be a small cyst several millimeters in diameter filled with brownish contents. Grayish, somewhat

homogeneous areas were occasionally distinguishable in the tumor. On histological examination the superficial squamous epithelium was usually found intact. It might be normal or thickened. The stroma of the growth was composed of dense fibrous tissue; sometimes a few bundles of nonstriped muscle were noted here and there in the fibrous tissue. In other specimens the nonstriped muscle was more abundant than was the fibrous tissue. Scattered throughout the field were glands, round, oval, or irregular. They occurred singly or in groups, and were lined with cylindrical epithelium. When occurring singly they frequently lay in direct contact with the fibrous tissue, but when found in groups were usually surrounded by a characteristic stroma that stained deeply and was much more cellular than the surrounding fibrous tissue. The cells of this stroma between the glands usually had oval or round vesicular nuclei. Frequently some of the glands were dilated and their epithelium was somewhat flattened. The cyst spaces noted macroscopically and filled with brownish fluid were likewise dilated glands, and the fluid was old blood. The stroma around the glands frequently showed fresh hemorrhage or remains of old blood to be recognized by the deposits of blood pigment. From the above description it was clearly seen that the gland picture was that of the characteristic uterine mucosa with its typical glands and its characteristic stroma, and further that the typical menstrual reaction was often present, as evidenced by the pains in the nodule at the periods, the accumulation of old menstrual blood with the formation of the small cysts, and in at least one instance by the occasional discharge of blood from the umbilicus.

Where Shall the Line Be Drawn Between Medicine and Surgery in Borderline Cases?—Dr. James E. Moore of Minneapolis said that all diseases of the thyroid, except malignancy and tumors, were medical in the early stages, because at that time a majority of them could be cured without operation. Many of them became surgical when neglected, or when non-surgical treatment failed. A case of goiter became surgical as soon as it gave serious symptoms which failed to yield to proper medical treatment. The danger was that it might be kept on the medical side of the border line until the best time for operation had passed. Diseases of the breast were always surgical. In face of the facts that eighty per cent. of tumors of the breast were malignant, and the mortality of cancer without surgical treatment was one hundred per cent., it was difficult to understand how any man could have the temerity to treat a nodule in the breast by any but surgical means. Every man who examined a nodule in a breast assumed a grave responsibility, and he owed it to himself as well as to his patients to give a positive opinion or to admit that he was unable to do so. It was a crime to paint a nodule in a breast with iodine and await developments, for the chances were that in four out of five cases it was malignant, and when it was malignant the patient's only hope was in an early operation. Most diseases of the stomach were still on the borderline. Malignant disease here, as elsewhere, was always surgical, and when medical men, laboratory men, and surgeons, by their combined efforts, would have arrived at a means of early diagnosis, as large a percentage of cures would follow surgery here as elsewhere, because this organ was very tolerant of surgery. All gastric ulcers were primarily medical because when promptly recognized the vast majority of them would recover under intelligent medical treatment. They became surgical when they caused perforation, persistent or recurrent hemorrhage or stenosis, and when for lack of or in spite of intelligent medical treatment they became chronic with thick walls and hardened bases. The present surgical treatment of gastric ulcer by gastroenterostomy was far from satisfactory. Dilatation of the stomach without stenosis was always medical. Surgeons had tried various methods for the relief of this condition, but had failed to secure satisfactory results. Diseases of the gall-bladder were practically all surgical. Medicine could do nothing for gallstones, or for an infected gall-bladder. Most diseases of the liver were medical, for up to the present time surgery had demonstrated a very limited field of usefulness. The kidneys furnished many borderline cases. In the presence of stone or pyogenic infection all agreed that the treatment should be surgical. The treatment of Bright's disease by decapsulation had been advocated and practised by a few, but had not afforded sufficient encouragement to give it a definite place in surgery. Visceroptoses had swayed back and forth across the boundary line, but at the present time experienced surgeons quite generally agreed that surgery was a failure in these conditions. Tuberculous peritonitis was still on the borderline, for it was an open question in the minds of both physicians and surgeons as to how these cases could be most successfully treated. Tuberculosis in all parts of the body furnished many borderline cases, and whether treated medically or surgically there was certainly great opportunity for improvement over our present methods.

Dr. Herman J. Boldt of New York City stated that there were a number of women who had a chronic catarrhal inflammation of the appendix, whose cases might be classed as on the borderline. He referred to women especially who had fat abdomens, who were to a greater or less degree neurasthenic or psychasthenic, and who could be cured by intelligent medical care, general hygiene, massage, etc. There were a number of women who were constipated, and who would get well by intelligent medical treatment. There was another large percentage of patients who had pelvic conditions which were on the borderline between medical and surgical treatment; consequently it behooved the practitioners to carefully study these cases and to give them the benefit of the doubt before resorting to operations which would cause the destruction of a function which was of vital importance to womanhood.

Dr. Samuel Lloyd of New York City could not agree with Dr. Moore with reference to decapsulation of the kidney. A young man, twenty-six years of age, was brought into his office some years ago, waterlogged, having one or two convulsions a day and threatened with death. The physician who brought the patient asked Dr. Lloyd to do a decapsulation of the kidney, and the latter said the patient would die on the table, and he would not do it without the consent of the family. The family united with the physician in the request. He decapsulated the patient's kidneys, they began to functionate normally in a short time thereafter, and the patient went through four years of active life. He felt confident that without decapsulation of the kidneys this patient would have died.

Dr. Robert S. Hill of Montgomery, Alabama, took exception to Dr. Boldt's remark about chronic appendicitis. A man with chronis appendicitis was like a man with a stick of dynamite in his side, and we were not justified, when we considered the small mortality of the operation, in allowing this man to go around doing his work, depending upon the general practitioner to handle him with care. This condition was frequently responsible for the neurotic conditions, and no case, such as Dr. Boldt described, should be turned over to the general practitioner.

Dr. Moore, in closing, said that he was firmly convinced that acute appendicitis was the result of chronic appendicitis; therefore, to avoid acute appendicitis and all its dangers, which was carrying away its thousands, we should remove all chronically inflamed appendices.

The Colon Bacillus, a Regulator of Population.—Dr. Robert T. Morris of New York said that disturbances

of the balance of nature by over-population of a locality with some animals, like rabbits and lemmings, was met by nature with epidemics, which rapidly reduced the numbers of these animals. In the early days of history the human species was subjected to similar epidemics. Preventive medicine had taken charge of most of these, and over-population was controlled by nature through endemics, toward which the decadent individuals were most vulnerable. Nature set a limit to the stage of development which might be attained by various animals, including man, and by species of plants. After an allowable stage of development had been reached, nature poisoned off what she seemed to consider the excessive number of individuals or undesirable individuals. This poisoning was accomplished in the plant and animal world by the toxins of various bacteria, chiefly. Preventive medicine had taken up one after another various bacteria engaged in endemic destruction of individuals. Until recently the tubercle bacillus was believed to be the most important among these. Now that the tubercle bacillus was under good control, perhaps we should find that the colon bacillus had stood next in order as nature's agent against over-population. Bacteriologists told us for many years that the colon bacillus group was nonpathogenic and even useful when at home in the bowel They did not put detectives upon its track when away from home restraints. Flagrant infractions were first noticed when the colon bacillus was found to be destroying the appendix or causing a cholecystitis, or an abcess of the kidney, but the acute demonstrations of the harmful influence of the colon bacillus comprised only a very small part of its work. The insidious influence of the colon bacillus and its toxins promised soon to be revealed as one of the most important in the history of disease. This bacterium was not only the direct cause of a large number of diseases, enumerated by the speaker, but it seemed to pave the way for a number of terminal infections, and it was the dominant but overlooked factor in such a range of ailments that we might fairly place it in the classification as one of nature's trusted agents for limiting population.

Benign Tumors of the Stomach.—Dr. Edward A. Balloch of Washington, D. C., said that benign tumors of the stomach, while comparatively rare, had been reported in sufficient numbers in the aggregate to make it necessary to consider them in the diagnosis of intra-abdominal disease. All forms of benign growths had been reported. According to their nature, they might originate from one or another coat of the organ. They seldom gave rise to symptoms unless they projected into the stomach or were so situated as to give rise to obstructive symptoms. Pyloric growths came in the latter category A small growth here would cause more trouble than a larger one elsewhere. For this reason none of the reported pyloric growths had been very large. The main question of interest in connection with these growths was that of diagnosis. No one reporting a case seemed to have made a correct diagnosis. With the pyloric growths the suspicion had been that the obstructive symptoms were due to malignant degeneration. In the case of growths elsewhere they had been referred to the kidney, the intestine, the omentum, or to the pelvic organs. The author reported two cases, one a personal one, and the other occurring in the practice of another surgeon. His own case occurred in the person of a woman, fifty-six years of age, unmarried. There was a history of a severe fall twenty years before, when the left side was severely injured. Vague dyspeptic symptoms for several years, principally pain and nausea, were related. The pain was worse after the menstrual periods. Enlargement of the abdomen was first noticed December, 1910 This had steadily increased, and, at the same time, the pain and nausea had grown worse. Examination showed a mass in the lower left quadrant, having the general size and shape of a kidney. It could be easily pushed into the left kidney region, but resumed its original position when pressure was removed. A diagnosis of wandering kidney was made and the patient sent to the hospital for operation. After she was anesthetized a further examination was made, when it was found that the mass could be pushed all over the abdomen. The diagnosis was then made of omental cyst, or a pelvic tumor with a long pedicle. After opening the abdomen the growth was found to spring from the greater curvature of the stomach. It was removed without difficulty and the patient made a rapid recovery. Pathological examination showed the growth to be a soft fibroma. The author expressed the opinion that the greater mobility of these growths was the principal criterion in their diagnosis. However, as this mobility was likewise an accompaniment of intestinal and omental growths, one must consider the symptoms in the case in differentiating these classes of growths. The operative features of these tumors presented no special difficulty.

Pyloric Stenosis Due to Overgrowth of Scar Tissue: "Gastric Keloids."—Dr. W. M. Jordan of Birmingham, Alabama, said that judging from his personal experience, nonmalignant new growths in the pyloric end of the stomach were much more common in the negro race than in whites. He had not observed a single case of this character in a white person, but had met with five cases in negroes If he ventured to suggest the term "gastric keloids" as descriptive of these growths, he would not wish to be understood as attempting to draw an exact pathological parallel between the keloids of the skin and stomach tumors herein described, but rather as undertaking to point out the anology between the two conditions, and to borrow a familiar clinical term to apply to an otherwise nameless condition. There were two men and three women, whose ages were respectively 28, 29, 38, 45 and 55. All gave stomach histories more or less suggestive of ulcer preceding the onset of obstruction. The smallest growth was the one which was resected. It as about one inch in diameter, while the largest was as broad as the hand. In every case the tumor was situated to the stomach side of the pylorus. In all but one the growth merged with the pyloric ring at one end and presented a sharply defined border at the other. The peritoneum overlying the growths was apparently normal. When the stomach was put on the stretch, as in lifting it out of the incision, the gastric wall overlying the tumor assumed a whitish, bloodless appearance, which made it easy to demonstrate the outline of the growth In one case the operation was partial gastrectomy, while the other four were treated by posterior gastrojejunostomy. Complete relief was noted in every case.

Dr. D. Edward Gavin of Mobile, Alabama, reported a case of congenital hypertrophic pyloric stenosis which was successfully treated surgically.

Dr. James E. Thompson of Galveston, Texas, said it had occurred to him in listening to the paper of Dr. Balloch, we might probably classify these cases more correctly as cases of myoma. Three years ago he read a paper on myoma of the stomach and collected a number of such cases. He found at that time that myosarcomata were moderately common They were extremely common in horses. In regard to the paper of Dr. Jordan, who made a comparison between fibroma of the uterus in the colored race and inflammatory tumors in connection with the pylorus, the speaker did not think they were fibromata, but myomata.

Dr. James E. Moore of Minneapolis, said, in speaking of tumors of the stomach, or tumors of the character under consideration, occurring in unusual places in the abdomen, it was well to bear in mind the possibility of their being parasitic growths, that is, having been original

growths from the uterus, they had become attached to the other viscera, and later nature made a separation. Many such cases were on record.

Dr. Balloch, in closing the discussion on his part, said at first he was very much of Dr. Thompson's opinion that this tumor looked very much like a sarcoma. It was pronounced by the pathologist a fibroma, and as there were no muscular elements in it the speaker had difficulty in conceiving how a soft fibroma could occur in that locality.

Dr. Jordan, in closing, said it was not his idea to draw a pathological parallel between these growths and anything else. He had gotten into the habit of calling them stomach keloids, not knowing what else to call them. It was not his purpose to claim that they were similar to fibroids of the uterus.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE

SECTION ON PEDIATRICS.

Stated Meeting, Held December 14, 1911

Dr. William Shannon in the Chair

A Case of Chondrodystrophy.—Dr. George Dow Scott presented this patient, a female child about nineteen months old. No history of syphillis or drunkenness in the parents or grandparents could be obtained. The child was born normally. She showed marked characteristics of the disease, the large overhanging head, the small tipped nose, the shortened long bones, the late dentition, the open fontanelle, the cuffed skin of the legs, rachitis, feeble musculature, inability to stand, and a marked kyphosis of the lower spine. An enlarged thymus gland was present. This condition had been confounded with syphilitic rachitis, hydrocephalus, and cretinism. Dr. Scott presented pictures of the bones on the screen which showed well the relationship of the epiphyses to the diaphyses. The thymus gland could also be seen.

A Case of Chondrodystrophy.—Dr. L. E. La Fétra presented a baby four weeks old, which showed a marked degree of deformity and dystrophy. He exhibited *x*-ray plates which showed the characteristic shortening of the arms and legs, a peculiar bending of the tibia and for purposes of comparison *x*-ray pictures were shown of a normal baby three weeks of age. The difference in the length of the bones was very marked and the shortening of the humerus, the tibia, and the femur was especially noted. The medullary cavity in all the bones was seen to be much wider than normal. Very marked exophthalmos was present in both eyes.

Dr. Charles Hermann said that these two cases were very interesting and together gave a complete picture of this condition. Dr. La Fétra's case showed a distinct exophthalmos which was rare in this condition. The radiograph showed not only the curvature of the shaft and the enlargement of the epiphyses, but a distinct change in the articulation at the knee. Dr. Scott said that in his case the thymus was slightly enlarged, which seemed peculiar in view of the fact that several authorities had advised the use of the extract of the thymus gland in these cases. In the Vanderbilt Clinic two such cases were at present under treatment. Some years ago he had tried the extract of the pituitary gland, but without marked effect. However, he thought its use was less empirical than the use of thymus extract.

Dr. Walter Lester Carr said these patients were certainly not normal; although they might be quick and alert they did not conform to the normal child. Some of them were precocious but their normal development was uneven, and sexually they were overdeveloped.

Dr. Ward B. Hoag said that the question of the differential diagnosis of cretinism from chondrodystrophy had been raised; while there were many physical points of resemblance between the two conditions, the marked difference in mentality should make the differential diagnosis fairly easy. There was practically an absence of mentality in the positive cretin, whereas in the individual affected with chondrodystrophy the mentality was not affected to any marked degree although they might be slow or backward.

Dr. George Dow Scott asked if these children's minds were really normal. He believed that they were undeveloped mentally.

Demonstration of a New Method of Obtaining Blood Pressure in Children.—Dr. B. Raymond Hoobler read this paper. (See Vol. 80, page 1323.)

Abdominal Cystic Tumor in a Girl Ten Years of Age.—Dr. Sara Welt-Kakels reported this case. The girl was brought to Mt. Sinai Hospital in the latter part of October, 1911. There was nothing of importance in her family or personal history except that she had suffered from bronchitis a great deal and had been kept from school for four months on account of her cough. During this time she gained eight pounds. Some eighteen months ago the mother noticed that the child's abdomen became larger. She was frequently nauseated after eating but rarely vomited; she had obstinate constipation, and frequent micturition, and occasionally complained of slight pain in the right iliac region. She was at present fairly well nourished, but pale; she weighed 68½ pounds, she had no Hutchinson's teeth; the skin and visible mucosa were normal. The tonsils were slightly hypertrophied. Upon inspection considerable enlargement of the lower abdomen was observed, but no venous distention, and there was no protuberance of the umbilicus. The greatest circumference of the abdomen was 27¾ inches; the distance from the umbilicus to the symphysis was 8 inches. On palpation, a large smooth tumor was felt; it was cystic and rather tense and pressed against the anterior abdominal wall, extending from above the symphysis to about 1½ inches above the umbilicus. Fluctuation could be readily obtained. The tumor was very slightly movable and occupied nearly the entire front of the abdominal cavity and did not seem to be connected with any of the abdominal viscera; rectal examination confirmed the latter observation. Evacuation of the bladder did not seem to change the contour of the tumor. The blood, urine, and feces of the patient did not reveal anything abnormal. They had concluded that this was most likely an ovarian cyst. In the differential diagnosis, cystic tumors of the kidneys, liver, omentum, and mesentery had to be considered, and also cysts having their origin in remnants of the omphaloenteric and Wolffian ducts.

Hirschsprung's Disease in a Boy of Seven Years.—Dr. Sara Welt-Kakels presented this case. The family history of the patient showed nothing abnormal, except that the mother had given birth to a child that died on the eighth day, never having had a movement of the bowels. The patient had been constipated from the time of his birth, the first movement occurring the third day after birth, after glycerin enemata and laxatives had been administered. A few days after birth the abdomen appeared to be large and distended. The bowels moved only once in two or three days and the movements were small. During his second year the child grew rather worse, at one time being constipated for thirteen days. The sphincter of the anus was stretched and a tube inserted through which large masses of feces were evacuated. Following this the child improved, but after two months he again became worse. In his fourth year he had diphtheria, and subsequently became weaker, not walking much, but preferring to lie down and sleep. At that time he came under Dr. Kakels' observation. He then weighed 29 pounds; the circumference of his abdomen measured 27 inches; the distance from the xiphoid process to the um-

bilicus was 7½ inches, and from the umbilicus to the symphysis 5½ inches. The umbilicus did not protrude. The superficial veins were distended and movements of the intestines were visible through the abdominal walls. Percussion all over the abdomen showed tympanitis, but there was no tenderness on palpation, and no resistance could be felt anywhere. Digital examination showed the tonus of the sphincter somewhat increased, but Foges' proctoscope could be introduced without difficulty and it led into a spacious cavity; at the upper end of it small, hard fecal masses could be seen. The tympanitic distention of the abdomen, visible peristaltic action of the intestines, obstinate constipation, occasional vomiting and abdominal pain, and the fact that symptoms had been present from birth supported the diagnosis. Blood, urine, and feces did not show anything abnormal. The etiology of this rare disease was not quite clear. Danziger had collected 110 cases in the literature in 1907, including his own son, an infant of three weeks. Hirschprung assumed that in this disease there were a congenital dilatation and hypertrophy of the colon, a partial gigantism. Others believed that there was only a congenital dilatation of the gut, that the hypertrophy was compensatory, and that the stagnation of the contents of the gut caused the hypertrophy. Others again believed that there was only an undue length with a multiplicity of flexures of the gut at birth which led to dilatation and hypertrophy. Marfan maintained that a functional stenosis might result from an anomalous position of the sigmoid flexure in its relation to either the colon descendens or the rectum, which might again be responsible for the stagnation of the contents; in a smaller number of cases volvulus of the sigmoid flexure, anomalous valves, etc., were found forming a mechanical obstruction. The prognosis on the whole was not favorable, although occasionally patients might reach an advanced age. Death occurred not so often from complete obstruction of the bowels as from colitis, ulcerations, and perforative peritonitis. The most urgent indication was the removal of accumulated feces; in Concetti's case about 10 kilos of feces were removed by high irrigations. Permanent drainage, massage, and electricity applied to the abdominal walls together with proper dietetic measures were applicable to these cases. The outlook for recovery was better when they resorted to surgical treatment. The establishment of an artificial anus had been proposed, as well as resection of the large intestines, anastomosis, and colopexy. According to Danziger's statistics of 35 cases operated upon, 21, or 60 per cent., were cured, while of the 50 cases not operated upon 44, or 74.6 per cent., died.

Acute Glandular Fever in Children.—Dr. SIDNEY V. HAAS said that although a score of years had passed since E. Pfeiffer first read a paper describing this disease, and although the condition had since been recognized and written about by many other observers, there was still much discussion as to whether such a condition existed *sui generis*, or whether it represented a state of glandular enlargement secondary to infection of the nasopharynx or mouth, or perhaps an abortive form of some disease having glandular swelling as an accompanying symptom. The chief argument of those opposed to considering the condition as a separate disease was that the glands involved drained the nose, nasopharynx, pharynx, and mouth, and that through these the more distinct group of glands became involved, and hence the symptom-complex was only a manifestation of glandular enlargement due to a regional infection. The symptoms characterizing glandular fever and those which refused to fit into any other disease were fever and malaise, acute swelling, and tenderness of the glands of the neck, accompanied by a lesser involvement of the entire glandular system. The disease occurred in both sporadic and epidemic form, the latter seemingly the more common. Perhaps this was because single cases went unrecognized, or were classed as adenitis. Park West described an epidemic of 96 cases among forty-six families extending over a period of three years. Many smaller epidemics had been reported. In New York City, in the spring of 1911, there was an extensive epidemic. Dr. Haas said that in his private practice from February 20 to June 2 there had been 12 cases in 10 families, and in the out-patient services of Vanderbilt Clinic and Lebanon Hospital he had seen many others. From a study of the previous history of these cases the fact was brought out that symptoms of the exudative diathesis existed in every instance as shown by charts. Perhaps further experience would demonstrate that this condition was a predisposing factor. The fact that epidemics had been reported by Pfeiffer, Rauchfuss, and others made it appear that the condition was contagious. Again, when the disease entered a household where there were other children, one or more usually became affected. The affection was essentially one of early childhood, the overwhelming number of cases occurring under the age of ten, and most of these under the age of five years. There seemed to be no predilection for either sex, and social condition did not seem to be a factor. More cases occurred during the spring months than at any other time. The pathology of glandular fever was still obscure, though there seemed to be evidence pointing to the streptococcus infection at least as the cause of complications. It seemed not unlikely that more than one organism might be responsible for the condition. Cultures taken from the throats of patients showed streptococci, staphylococci, pneumococci, and influenza bacilli. Streptococci in pure culture had been found in two cases reported by Shaffer in broken-down glands; in two cases reported by Bothowsky and Korsakoff that came to autopsy streptococci in pure culture had been found in the cervical and axillary glands, and in the liver, spleen, kidneys, medulla of bones and heart's blood. Morsakoff took cultures of the urine in five cases complicated by nephritis and found streptococci in pure culture in three of them. According to Park West the incubation period in glandular fever was about seven days. The onset of the disease was usually sudden, though slight fever and malaise might precede the outbreak by a day or two. There were usually a variable degree of prostration, pain in the limbs, irritability, moderately rapid pulse, and occasionally vomiting and pain in the abdomen. There was usually pain in the throat. There was usually a slight coryza and a slightly congested pharynx. The temperature ranged from 102° to 105° F., the pulse from 100 to 140, with the respiration in normal ratio to the pulse and temperature. An enlarged gland would be found at the angle of the jaw which, even in the early stages of the disease, would cause the head to be held rigid in the position of torticollis. Swallowing was painful and the glands were exceedingly tender. The chest and circulatory system were usually negative. Within from twelve to forty-eight hours after the onset of the disease the gland at the angle was masked by a large and very tender mass, just beneath and posterior to the upper end of the sternomastoid muscle, and varying in size from a pigeon's to a goose egg. The glands along the anterior border of the sternomastoid muscle, and the posterior servical, supraclavicular, submental, submaxillary, and parotid glands, and the fine network of glands that covered the lateral and posterior aspects of the neck became enlarged, and the axillary, epitrochlear, inguinal, and mesenteric glands likewise frequently became affected. The glandular swelling was bilateral, although not always synchronous. In some cases the liver and spleen became palpable after a few days, but not regularly. In some instances the fever and prostration disappeared in from one to three days and the glands gradually diminished in size, while in others, after a moderate fever for a few days, there was a sudden rise in

temperature to 104 or 105 F., the glands enlarging until they assumed the size of goose eggs or smaller. After four or five days the attack subsided and the glands receded slowly, sometimes taking several weeks to become normal. The same group of glands might swell and subside several times, the exacerbations continuing for several weeks. The prognosis was good, although a few fatal cases had been reported. In atypical cases the differential diagnosis might offer some difficulties, but the entire absence of other physical signs and the quick changes in the size of the glands, the number of glands involved, the unusual localization and extreme tenderness, and the absence of blood changes characteristic of diseases having unusual glandular enlargement for a symptom, should suggest the diagnosis. Dr. Haas called attention to the points of difference between glandular fever and adenitis, Hodgkin's disease, leucemia, parotiditis, and calculi in the salivary ducts. When the condition became prolonged it had to be differentiated from malaria and from pyelitis: and if abdominal pain and tenderness were marked, from appendicitis. The complications encountered in a small number of cases were nephritis and a systolic mitral murmur, which appeared to be hemic in character and regularly disappeared after recovery. The failure to recognize glandular fever might lead to false and grave prognoses, and hence the disease was entitled to a place in all text-books on pediatrics which at present failed to mention it, and to a fuller consideration in those which did.

Dr. CHARLES HERMANN said that as long as the specific organism causing glandular fever was unknown, they were probing more or less in the dark. While the streptococci were frequently present, it was probable that they were secondary invaders. The nasopharynx would naturally be supposed to be the portal of entry, but this was by no means certain. The point of attack was frequently at some distance from the point of entry of the infectious material. Of this acute poliomyelitis was a striking example. It seemed likely that the virus of acute glandular fever had a special affinity for the cervical lymphnodes affected just as the virus of mumps had for the parotid gland. There were numerous examples of such selective action. There was not a very close relation between glandular fever and mumps. The incubation period was much longer in the latter and the age incidence was different. Glandular fever was not uncommon in infancy, whereas mumps practically never occurred in children under one year of age. The cases reported emphasized the close relation between the exudative and lymphatic diatheses.

Diagnosis and Treatment of Vomiting in Infants by Means of a Simple Duodenal Catheter.—Dr. ALFRED FABIAN HESS read this paper, in which he stated that it was possible to insert a soft rubber catheter (Nelaton No. 15 F.) past the pyloric sphincter and into the duodenum. The catheter was introduced in the same way as an ordinary stomach tube, and with some experience the technique became almost as simple. The main difference between this catheter and the duodenal tube previously described by Dr. Hess was that the catheter did not depend upon gravity or peristalsis to direct it to the pylorus. The force of inserting it propelled it along the natural path of the food to the pyloric opening. This gave it the additional advantage of a probe with which one might test the tonicity and irritability of this sphincter. Radiographs showed that the catheter invariably, on entering the stomach, bent sharply to the left to reach the fundus, and that therefore the more vertical position of the stomach of the infant, did not account for the ease with which the catheter entered the duodenum. It was probable that, unknowingly, others had entered the duodenum by this method, and that reports on the capacity and contents of the stomach had been open to sources of error from this source. By means of the catheter they could readily diagnose pylorospasm, and differentiate it from vomiting from other causes. In cases of spasm a persistent resistance was encountered at the same point whenever they attempted to advance the catheter; this was frequently accompanied by sensitiveness of the pylorus. Failure to traverse the pylorus after repeated attempts was proof of the existence of marked pyloric stenosis. A mild degree of stenosis, sufficiently slight to permit the catheter to pass, could not be differentiated from simple spasm. Cardiospasm frequently accompanied pylorospasm. This sign had been frequently overlooked because of the too forcible insertion of the stomach tube. If a soft rubber tube was introduced into the esophagus, it might be found impossible to enter the stomach. This spasm frequently prevented the food from entering the stomach, it being checked at the cardia. An increased duodenal secretion frequently accompanied pylorospasm, just as did a marked gastric secretion. This secretion was found to contain protease, lipase, and amylase to a marked degree, so that in this connection one might speak of a pancreatic hypersecretion or succorrhea. There were cases of cardiospasm and pylorospasm not accompanied by increased gastric secretion. In a case of this kind there was no pancreatic hypersecretion. The catheter was of value in the therapy of pylorospasm, as its passage through the pylorus seemed to relax the ring and thus to diminish the vomiting. It would be of advantage to pass the catheter frequently in such cases. Another form of therapy consisted of duodenal feeding, which radiographs had shown to be feasible. However, it should be reserved for such cases as did not retain food given by gavage, and should be given slowly and in not too large amounts. It had been found to be of great value in cases of this kind.

Why Our Obstetricians Should Either Extend Their Line of Endeavors or Confer Earlier with the Pedotrophist."—Dr. WARD BRYANT HOAG read this paper, in which he referred to the great awakening on the part of both the medical profession and the laity in regard to the causes of infant mortality. Commendable endeavors were being made on all sides for the care and restoration to health of sick infants, but apparently only meager thought, and this from the medical profession, was being given to the conservation of the health and strength of the infant from the time it came into the world. A little discreet advice for the baby at birth, and a little "follow-up" supervision afterward were better than a great deal of endeavor after the baby had needlessly been allowed to develop nutritional disturbances. At present there was no recognition of a specialty in work among children which applied to what might be called "prophylactic work" or simply "care of children." Pediatrics was defined as relating to the diseases of children and their cure. With these facts in mind the writer had consulted with the occupant of the Chair of Greek in Columbia University for an appropriate word to express this field of endeavor, and the word "pedotrophy" had been suggested. This word meant "care of children." In their work with children the greatest possibilities lay along protective and preventive lines. The time was ripe for the schools and specialists to extend their usefulness by recognizing the prophylactic specialty of childhood work, pedotrophy. Twenty per cent. of all children born died during the first year of life. Of all births recorded in the Greater City of New York, 43 per cent. were attended by midwives, and, although there were no statistics, the mortality among these was unquestionably high. Gastrointestinal diseases caused the death of from 60 to 75 per cent. of the infants that died during hot weather, and from one-third to one-half of each year's victims died

before the third month of existence. In the Borough of Manhattan in August, 1900, of the 1,081 deaths under one year of age, 331 died of gastrointestinal diseases and 325 died before the third month of age. During the same month 15 died from nutritional diseases during the first week of life, 24 died during the second week of life, 27 during the third week, and 109 during the fourth week. This large increase in mortality for the fourth week was characteristic of all months of the year. It seemed apparent, if not indisputable, that there was some radical defect or neglect on the part of those who should early advise regarding the child's nutrition and care; that mothers were left largely to their own initiative until the child became sick. The best obstetricians in this city, and they had no superiors the world over, admitted that they took little thought regarding the many details influencing infant nutrition and care. This advice was largely left to the nurse, and she too frequently failed to fill the breach. This failure on the part of obstetricians was further emphasized by the fact that in most of our large lying-in institutions no part of the regular attending staff was made up of practitioners who gave special thought to infant feeding or questions pertaining to infants in general. After entering a vigorous protest against the nefarious practice of midwives, Dr. Hoag said that the attitude of the general practitioner was much the same as that of the specialist. They all thought too little about the infant during the first days, and only began their endeavors after much damage had been done from following general principles or the advice of those about the house. As for the remedy, what had been done could be repeated; possibly it could be improved upon. In institutional work, that of the Free Out-Door Maternity Clinic, conducted by Dr. I. L. Hill and Dr. Herman Schwarz of New York City might well be considered a model. Those interested in this line of work should study their report for 1909. Of 784 children born under their charge from November, 1908, to November, 1909, 38 died and 105 passed from their attention. This brought the mortality well under 6 per cent., a very marked contrast to the general mortality reported in the city. This work was among the very poor. In private work the writer was conversant with the records of 117 born between 1905 and 1909, where but two failed to live one year because of nutritional diseases, a mortality of less than 2 per cent. All lying-in institutions should have an attending pedotrophist, who should assume to advise from birth on all questions concerning the baby. The mothers should be taught the fundamental care of the baby during their stay in the institution. When the mother and child left for home there was a well-trained baby and a mother with some definite idea of her responsibilities as a mother, a mother who knew what she was expected to do for her baby and how to do it. The mother thus taken into the confidence of her physician respected only the advice that came from a physician, and would seek his advice rather than that of some old woman who called on her. Among the poor the "follow-up" work and advice of a trained nurse were invaluable, both to the baby and to the household in general. In private practice certainly no less was due the mother than in the institution. If the surgeon did not care to properly instruct the mother, he should have an associate who should attend to this work.

Dr. George L. Broadhead thought that Dr. Hoag's paper was a valuable one, but that he was inclined to be too severe on the obstetrician and the general practitioner. He did not think that as a class they paid so little attention to the details concerning the nutrition of the infant under their care. The day had long since passed when the duty of the obstetrician ceased when he tied the umbilical cord and handed the baby over to the nurse. It seemed to him that the child was deserving of at least as much attention as the mother. The results obtained by Dr. Hill and Dr. Schwarz in the Free Out-Door Maternity Clinic were certainly excellent. Every mother should be instructed to bring her baby to the dispensary connected with the institution in which she had been confined. There were excellent dispensaries in connection with a number of the maternity hospitals in the city. No obstetrician or general practitioner should neglect this, that the mother was properly instructed as to how to care for her infant. With all the clinics and facilities at hand here in New York, Dr. Broadhead could not see why babies should not be properly treated.

Dr. Floyd M. Crandall said that the paper had interested him because it was in the line of preventive medicine, and certainly great advances had been made in that direction. There were three classes of people who had charge of babies from the first day of life. The first was the obstetric specialists; among this class the improvement had been great during the past twenty years. The second class might improve very much; this class embraced the general practitioners who did much obstetric work and paid but little attention to pediatrics; it was a hard proposition to know just how to deal with them. They were the worst kind of baby-weaners, usually telling the mother to buy a certain kind of baby food and use it according to directions. Midwives formed the third class. Much could be accomplished by following up babies when the birth report went in, but often this report did not go in until a week or more after the birth of the child, and by that time the damage was done. The first week was one of the greatest importance to the baby's welfare.

Dr. George Dow Scott said that in his work in this line in New York City and in Boston he had been impressed with the fact that the mother's breasts were so often neglected. More attention should be paid to the breasts of the mother, as well as to her diet, and this would tend to make the milk better, give her less trouble in nursing her baby, and lessen her desire to wean the baby from the natural milk.

Dr. Charles Hermann thought Dr. Broadhead was speaking from the theoretical standpoint: it was not sufficient to tell the mother simply to come to the dispensary. There was great trouble in getting the mothers to return. On this account the visiting nurse was indispensable.

Dr. Ward B. Hoag, in closing the discussion, said he did not wish to criticize any one class of men; his remarks were to be considered as one more effort added to the many already devised to lower the infant mortality. The large mortality of infants during the third week of life was evidence of some radical defect in the advice given during the first week. Too many bottle-fed babies came from the lying-in hospitals, and too often the instructions given concerning the contents of the bottle were such that it was evident proper consideration had not been given the subject.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Ohio State Medical Board.

June 6 to 8, 1911

ANATOMY.

1. How and where is the clavicle attached to the scapula?
2. What are the different kinds of motion of the elbow joint, and name the bones entering into its formation?
3. Name the ligaments of the hip joint.
4. Name the muscles that flex the thigh, also the leg.
5. Give the course and subdivisions of the subclavian artery.
6. Name the three divisions of the axillary artery.
7. Name the superficial veins at the bend of the elbow.
8. Give shape, location, dimensions and capacity of the stomach.

9. What are the divisions of the trifacial nerve? Name the branches of the third division.
10. Give the boundaries of the popliteal space.

PHYSIOLOGY.

1. What are the properties of protoplasm? What is its relation to nutrition?
2. What are the functions of organized cells?
3. Describe the white blood cells. What conditions affect their relative number, within physiological limits?
4. What salts affect the action of the heart and how?
5. What is the principal source of heat in the body?
6. What part of digestion takes place in the stomach?
7. What kind of food does the secretion of the liver assist in digesting? What other office has it?
8. Describe the portal circulation.
9. Describe the motor area of the brain.
10. Give the location of the center of vision. How is this determined?

MATERIA MEDICA AND THERAPEUTICS.

1. Name three external antiseptic remedies. Give indications and uses.
2. Name the various preparations of aconite and give dose of each. State therapeutic uses.
3. Iodine. Name principal salts and preparations. Give dose of each and state therapeutic uses.
4. What are the uses of narcotics? Name the principal ones giving the dose of each.
5. What preparations of mercury are used as cathartics? Give dose of each.
6. What drugs would you use in anemic conditions? Write two prescriptions including remedies recommended.
7. Potassium salts. Name the principal ones and give dose and use of each.
8. Why is atropine combined with morphine? Give dose of each.
9. What are the symptoms of opium poisoning? Give treatment. What class of people bear opium badly?
10. Discuss the dangers incident to the treatment by x-ray.

CHEMISTRY.

1. Name the constituents most frequently found in water which render it unfit for drinking purposes. Give test for each.
2. Name the albuminous bodies and give the source of each.
3. Name the principal inorganic acids. Give the properties and uses of one. Name the principal organic acids. Give their sources and properties and uses of one.
4. By what tests chemically applied would you determine whether a specimen of human milk was up to the standard?
5. Give a reliable method for determining the quantity of hydrochloric acid in the gastric contents.
6. Give the chemical nature of phenol, its properties, poisonous effect and antidotes.
7. Classify poisons from a physiological basis.
8. What is alum chemically, and when may it be used to improve an impure water supply?
9. Mention three different processes by which carbon dioxide is generated in nature.
10. What is the chemical name of tartar emetic? Give its poisonous effects and antidote.

DIAGNOSIS.

1. Describe reduplication of the heart sounds. What is its significance, and state in what diseases it may occur?
2. State diagnostic significance of mitral systolic murmurs.
3. Describe irregular pulse (arrhythmia) and state clinical significance of its varieties.
4. In what morbid conditions is dyspnea present?
5. What pathological alterations of the lungs cause a decreased resonance on percussion?
6. What diagnostic sign is furnished by diplopia?
7. In what pathological conditions is the liver generally found enlarged?
8. When is the knee jerk exaggerated, and in what affections does it occur?
9. Name abnormal constituents of the stools and state their pathological significance.
10. In what diseases does hiccough occur, and what diagnostic value is derived therefrom?

PATHOLOGY.

1. What is the pathology of follicular tonsillitis?
2. What pathological changes take place in senility?
3. Give the pathology of catarrhal appendicitis.
4. What is the basis of the opsonin treatment, and describe the effect of an injection of bacterial vaccine?
5. Give the pathology of tabes dorsalis.
6. Name the paths of bacterial infection; the paths of extension.
7. Give the pathology of tuberculosis of the hip joint.
8. What is the difference between an antitoxin and a bacterial vaccine?
9. Give the pathological anatomy of catarrhal bronchopneumonia.
10. What are some of the adulterations found in foods and how would you detect them?

PRACTICE.

1. How would you manage and treat a case of diabetes mellitus?
2. Give the causes, symptoms and treatment of acute Bright's disease.
3. Give the pathology, symptomatology and treatment of poliomyelitis.
4. Give pathology, symptoms and treatment of pericarditis.
5. Define rheumatic fever; give symptoms, complications and treatment.
6. Give etiology, symptoms and treatment of erysipelas.
7. Give diagnosis and prognosis of laryngeal tuberculosis.
8. Give diagnosis of aneurism of the descending aorta.
9. Give etiology and diagnosis of influenza.
10. Give pathology and diagnosis of cholera infantum. What hygienic precautions are essential to prevent it?

OBSTETRICS.

1. When the cord is around the child's neck, what serious results may occur? How obviate?
2. How would you determine the death of the fetus in utero?
3. What symptoms would indicate concealed hemorrhage?
4. Name the different displacements of the uterus and outline general treatment.
5. Give symptoms and treatment of cystitis.
6. Give symptoms and treatment of placenta prævia before term and at full term.
7. Name the diagnostic points of the fetal head and state their uses.
8. How would you manage a breech presentation, and what is the most dangerous complication?
9. Give symptoms and treatment of puerperal eclampsia.
10. Describe the formation of the placenta and decidua and give its use or function.

SURGERY.

1. What is the latest method of treating tuberculous sinuses?
2. What is hypodermoclysis? Give technique and formula for intravenous infusion, also the quantity you would use in an adult.
3. Give causes, symptoms and treatment of hip-joint disease.
4. Describe the most feasible operation for empyema of the antrum of Highmore.
5. How would you treat internal hemorrhoids?
6. Diagnose an infective exudate in the pericardial sac. How would you proceed to give relief?
7. Ligate the internal carotid artery. Give indications for so doing. What precaution is necessary?
8. What is plastic surgery? Give an example.
9. How would you treat acute septic infection?
10. What are echinococcus cysts? Where most frequently located? What is the prognosis?

DERMATOLOGY, SYPHILOGY AND DISEASES OF THE EYE, EAR, NOSE AND THROAT.

1. What is tinea tricophytina? Mention its principal varieties and give treatment.
2. Describe psoriasis. How is it differentiated from squamous eczema?
3. Describe acute eczema—its difference from erysipelas.
4. What is meant by the initial lesion of syphilis?
5. Describe mucous patches.
6. Define astigmatism. Mention its causes, symptoms and the means to improve the vision with lenses.
7. Describe iritis. Mention its varieties, causes and treatment.
8. Describe acute catarrhal laryngitis; give treatment.
9. Describe otitis media purulenta. What dangers may result?
10. What are the causes of nasal hemorrhage, and how can it be stopped?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

OHIO STATE MEDICAL BOARD.

June 6 to 8, 1911.

ANATOMY.

1. The clavicle is attached to the scapula: (1) At the acromion process by the superior acromio-clavicular ligament and the inferior acromio-clavicular ligament. (2) At the coracoid process by the coraco-clavicular ligament, the conoid ligament, and the trapezoid ligament.

2. THE ELBOW JOINT: (1) The articulation between the humerus and ulna allows of flexion and extension. (2) The articulation between the head of the radius and the humerus also allows of flexion and extension. (3) The superior articulation between the radius and ulna allows of pronation and supination of the hand.

3. *Ligaments of the hip joint:* Iliofemoral, cotyloid, transverse, capsular, and teres.

4. *Muscles that flex the thigh:* Iliopsoas, sartorius, rectus femoris, pectineus, gracilis, adductor longus, adductor brevis, tensor vaginæ femoris.

Muscles that flex the leg: Sartorius, gracilis, semitendinosus, semimembranosus, biceps, gastrocnemius, popliteus.

5. See Cunningham's "Anatomy" (1909), page 821; or Gray's "Anatomy" (1910), page 625.

6. The first portion of the axillary artery is above the pectoralis minor, the second part is behind that muscle, and the third part is below it.

7. *The superficial veins at the bend of the elbow* are: Radial, median cephalic, median basilic, ulnar, cephalic, and basilic.

8. See Cunningham's "Anatomy" (1909), page 1051; or Gray's "Anatomy" (1910), page 1271.

9. *Divisions of trifacial nerve:* (1) Ophthalmic; (2) superior maxillary; (3) inferior maxillary. *Branches of the third (inferior maxillary) division:* Masseteric, deep temporal, buccal, internal pterygoid, external pterygoid, auriculo-temporal, lingual, and inferior dental.

10. BOUNDARIES OF THE POPLITEAL SPACE. *Externally, above:* By the biceps. *Externally, below:* By the plantaris and external head of the gastrocnemius. *Internally, above:* By the semimembranosus, semitendinosus, gracilis, and sartorius. *Internally, below:* By the inner head of the gastrocnemius.

PHYSIOLOGY.

1. *Properties of protoplasm.* "Protoplasm is a semi-fluid substance which swells up but does not mix with water. It is transparent and generally colorless, with refractive index higher than that of water but lower than that of oil. It is neutral or weakly alkaline in reaction, but may under special circumstances be acid, as, for example, after activity. It undergoes stiffening or coagulation at a temperature of about 54.5° C. (130° F.), and hence no organism can live when its own temperature is raised above that point; it is also coagulated and therefore killed by alcohol, by solutions of many of the metallic salts, by strong acids and alkalies, and by many other substances."

Protoplasm has the properties of: Movement, irritability, ingestion, absorption, excretion, growth, and reproduction.

Nutrition is practically one of the properties of protoplasm, and includes ingestion and absorption as well as excretion. Nutrition is the resultant of these three processes.

2. *Functions of organized cells. Epithelial:* Absorption, protection, secretion, excretion, motion, and reproduction. *Connective:* Strength; elasticity; support; union; to form sheaths for vessels, muscles, nerves, etc.; protection; to form trabeculæ, etc.; to preserve body heat. *Muscular:* Contractility. *Nervous:* Conduction of impulses.

3. The white blood cells are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their *functions* are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

Conditions affecting their relative number, within physiological limits: Digestion, exercise, cold baths, pregnancy, and lactation.

4. *Salts affecting the action of the heart:* "Immersed in a solution of 0.7 per cent. of NaCl, an isolated frog's heart will retain its rhythmicality for some time, but it ultimately passes into a condition of diastolic relaxation. It is precisely the same with KCl, and if a solution of the same strength as that of NaCl is used the arrest occurs much earlier. The K ions and Na ions act precisely in the same manner; that is, they ultimately produce a condition of diastolic relaxation; moreover, K ions are more efficacious than those of Na. But with Ca ions it is different. A beating heart, if immersed in an isotonic solution of $CaCl_2$, ceases beating, but in a condition of systole (calcium rigor). If, however, a solution of NaCl is added the heart beat recurs and the strength of the contractions is increased."—(Lyle's *Physiology.*)

5. The principal source of heat in the body is muscular energy.

6. In the stomach proteids are converted into proteoses and peptones.

7. The secretion of the liver assists in digesting fats. *The other functions of the bile* are: (1) To aid in the absorption of fats; (2) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (3) to eliminate waste products of metabolism, such as lecithin and cholesterin; (4) it has a slight action in converting starch into sugar; (5) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (6) it has a very feeble antiseptic action.

8. See Cunningham's "Anatomy" (1909), pages 901 and 1120; or Gray's "Anatomy" (1910), pages 754 and 1327.

9. The *motor areas* are located and arranged on the cerebral cortex immediately in front of the fissure of Rolando. At the upper part of the convolutions in front of this fissure are areas connected with the movements of the lower extremities; then from above downward are located the centers for movements of the shoulders, arms, wrists, fingers, face, lips, tongue, and larynx and pharynx.

10. *The center of vision* is in the occipital lobes, and particularly in the cuneus. Removal of the right occipital lobe in an animal is followed by left hemianopsia, removal of the left lobe by right hemianopsia, and removal of both occipital lobes by total blindness.

MATERIA MEDICA AND THERAPEUTICS.

1. *Three external antiseptics:* Mercuric chloride, formaldehyde, and silver nitrate.

Mercuric chloride is used for washing the surface of a part prior to operation, also for injections and dressings; it should not be used for instruments or excretions.

Formaldehyde is used for disinfecting rooms, houses, instruments, furniture, and clothing.

Silver nitrate is used as a prophylactic against ophthalmia neonatorum, also in the treatment of that disease; also in local treatment of ear, nose, and throat diseases; in diseases of the skin, and for solutions in gonorrhea, urethritis, vaginitis, and other diseases of the genital tract.

2. ACONITE. *Official preparations, with adult dose:* Fluid extract, ℥j; tincture, ℥x. *Medicinal uses:* For fevers, some inflammatory conditions, in high arterial tension, in nervous palpitation of the heart, and congestive dysmenorrhea; also externally for neuralgia, pruritus, herpes, chilblains, etc. *Therapeutic effects:* First stimulates and then paralyzes heart and also sensory nerves; lowers blood pressure; dilates peripheral blood-vessels, is a respiratory sedative; reduces body temperature; is a diuretic and diaphoretic.

3. The official preparations and doses of iodine and the iodides are: Iodine, 1/10 of a grain; compound solution of iodine, 3 minims; tincture of iodine, 1½ minims; potassium iodide, 7½ grains; sodium iodide, 7½ grains; ammonium iodide, 4 grains; strontium iodide, 7½ grains; zinc iodide, 1 grain; diluted hydriodic acid, 15 minims; syrup of hydriodic acid, 1 dram.

"Iodine is alterant, rubefacient, vesicant, caustic, antiseptic, and parasiticide. It is used locally in the form of the tincture in sprains and bruises, over the chest in various lung troubles, in lupus, in chronic rheumatism, in pleurodynia and intercostal neuralgia, in ringworm, and in erysipelas. It is administered internally in diseases asso-

ciated with nutritional disorders, as tuberculosis in its various forms, in hypertrophy of the thyroid gland and tonsils, in cervical and ovarian cysts, and in the late stages of syphilis. It may be employed in inhalations. It is of value as a local application in rhinology, laryngology, and even in ophthalmology.

"The *iodides* are used to aid in the absorption of inflammatory products, as in pneumonia, pleurisy, etc., and in tertiary syphilis, chronic rheumatism, etc. In tonsillitis and sore throat they are used as a gargle (gr. 2/5 to ℥i). The most generally used iodide is that of potassium, dose, gr. 5-℥i in solution. Sodium iodide and strontium iodide are often used. Dose, gr. 5-℥ss. Ammonium iodide is the most irritant and most energetic in action. Dose, gr. 2-10. Hydriodic acid in 1 per cent. solution is frequently employed in the form of the syrup. Dose, ℥i-4. The compound solution of iodide, or Lugol's solutions, is given internally in doses of ♏i-5, diluted.

"The tincture of iodine is used locally only. An ointment of iodine may be applied locally in certain inflammations."—(Gould and Pyle's *Pocket Cyclopedia.*)

4. *Narcotics are used* to relieve pain, to induce sleep, to allay irritation and spasm. *Chief narcotics:* Opium, gr. jss; morphine, gr. ¼; hyoscyamus, gr. iv; stramonium, gr. j; cannabis indica, gr. j; also alcohol, ether, and chloroform.

5. *Preparations of mercury used as cathartics:* Hydrargyrum cum creta, gr. v; massa hydrargyri, gr. v; hydrargyri chloridum corrosivum, gr. 1/30; hydrargyri chloridum mite, gr. ij.

6. *For anemic conditions:* Iron, arsenic, manganese, nux vomica.

℞ Tincturæ ferri chloridi, ℥ij.
Acidi phosphorici diluti, ℥iij.
Spiritus limonis, ℥j.
Syrupi simplicis, q.s. ad ℥iij.
Misce. Signa: A dessertspoonful in water after each meal.

℞ Ferri sulphatis exsiccati.
Potassii carbonatis, ää ℥j.
Syrupi., q.s.
Fiant pilulæ, no. xxiv.
Signa: One pill after each meal.

7. *Potassium salts:* Carbonate, gr. xv; bicarbonate, gr. xxx; acetate, gr. xxx; citrate, gr. xv; sulphate, gr. xxx; bitartrate, gr. xxx; nitrate, gr. vij; chlorate, gr. iv; permanganate, gr. j; iodide, gr. vij; bromide, gr. xv; cyanide, gr. 1/5.

The *carbonate* and *bicarbonate* are used for itching and for skin diseases; the latter is also used for dyspepsia, rheumatism, gout, jaundice, and gallstones. The *acetate* and *citrate* are used for gout, rheumatism, in dropsy, renal diseases, cardiac diseases, and in general as diuretics. The *sulphate* and *bitartrate* are used as cathartics, the latter also as a diuretic. The *nitrate* is used (by inhalations of its fumes) in asthma. The *chlorate* is used for inflammatory conditions of mouth and throat. The *permanganate* is used for wounds, sores, ulcers, erysipelas, and as a douche in gonorrhea, gleet, etc.; also as an antidote to morphine poisoning. The *bromide* is used in epilepsy, insomnia, neuralgia, migraine, delirium tremens, convulsions, nymphomania. The *iodide* is used in syphilis, asthma, chronic rheumatism. The *cyanide* is used to relieve vomiting, gastrointestinal pain, and cough.

8. Atropine is often combined with morphine when the latter is used, for the following reasons: (1) To prevent nausea and insomnia; (2) to intensify the effect of the morphine, and so a smaller dose may suffice; (3) to neutralize the effect on the pupils. Dose of atropine, gr. 1/160; of morphine, gr. ¼.

9. The *symptoms of poisoning by opium* are as follows: "At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somnolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and, in fatal cases, dies in from forty-five minutes to fifty-six hours, usually in from twelve to eighteen hours. In cases of recovery after the stage of narcosis the pulse and respiration gradually return to the normal, and the condition of coma passes into one of deep sleep, lasting twenty-four to thirty-six hours."

Treatment "Wash out the stomach with a dilute solution of potassium permanganate, leaving about 500 c.c. in the stomach, and maintain the respiration. In the first or second stage the 'ambulatory treatment' should be adopted to prevent, if possible, the establishment of the third stage. If this stage develop the main reliance is to be placed in maintaining the respiration by artificial methods, until the poison has been eliminated. Strong coffee, or caffein, by the mouth or rectum, are of benefit. The same cannot be said of atropine. The urine should be drawn by the catheter."—(Witthaus' *Essentials of Chemistry.*)

Infants and children bear opium badly.

10. *The dangers incident to treatment by x-ray* are: Burns, dermatitis, and sterility.

CHEMISTRY.

1. Sewage, bacteria, lead, and refuse from factories. *Sewage* is detected by the addition of a few drops of potassium permanganate, which will be decolorized in the presence of organic (or oxidizable) matter. *Bacteria* are detected by making cultures and subsequent bacteriological examination. *Lead* is detected by the addition of hydrogen sulphide, which becomes darkened by any lead present in the water.

2. *Albuminous bodies: Protamines*, found in spermatozoa of some fish. *Histons*, found in red blood corpuscles and thymus of calf. *Globulins*, found in muscles, fibrin, and clotted blood. *Scleroproteids*, found in bone, cartilage, connective tissues, skin, hair. *Keratins*, found in skin, hair, nails. *Elastins*, found in yellow elastic connective tissue. *Collagens*, found in white fibrous tissue, gelatin. *Phosphoproteins*, found in milk and eggs. *Chondrin*, found in cartilage. *Neurokeratin*, found in sheath of medullated nerves. *Ossein*, found in bone. *Nucleoprotein*, found in the cells of the body generally. *Glucoproteins*, found in mucin and connective tissues. *Chromoproteins*, found in oxyhemoglobin. *Derived proteins*, found in the products of digestion of the proteins.

3. *Principal inorganic acids:* Hydrochloric, sulphuric, nitric, phosphoric, and boric. *Hydrochloric acid* is a colorless gas with a pungent, penetrating odor, a sharp, sour taste, acid reaction, and very irritant to the tissues. It is irrespirable and does not support combustion. It is only used for manufacturing purposes.

Principal organic acids: Acetic, citric, tartaric, butyric, tannic, lactic, and oxalic. *Oxalic acid* is a white crystalline solid, irritant, and with an acid taste. It is used for bleaching and removing stains.

4. The milk may be tested by taking the specific gravity, using Feser's lactoscope and the centrifuge.

5. *To determine the quantity of free hydrochloric acid in the gastric contents:* "To 10 c.c. of the filtrate decinormal sodium hydrate is added in such a quantity that a drop of the mixture no longer responds to Gunzburg's phloroglucin-vanillin test. The amount of the decinormal soda solution used multiplied by 10 gives the figure of the free hydrochloric acid. The percentage of free hydrochloric acid can be obtained from this figure by multiplying it by 0.00365."—(Einhorn.)

6. *Phenol* is phenyl hydroxide, C_6H_5OH. It is also called carbolic acid, but it is not an acid, nor is it an alcohol. Pure phenol is a colorless crystalline solid with a characteristic odor and an acrid burning taste, soluble in 15 parts of water, and freely soluble in alcohol and ether; it is a powerful antiseptic, coagulates albumin, and prevents fermentation.

Symptoms of poisoning: The skin and mucous membrane (where either has been in contact with the phenol) are hardened and whitened. There are burning pains in the mouth, esophagus, and stomach; vomiting, stupor, lowered pulse and temperature, contracted pupils, syncope, collapse, and death; the urine becomes discolored (greenish or black).

Treatment: Administer albumin, saccharated lime, sodium sulphate, or alcohol; then wash out the stomach.

7. Poisons may be classified (from a physiological basis) as: Corrosives, irritants, neurotics, septic poisons, and gaseous poisons.

8. *Alum*, chemically, is a double sulphate, being aluminium ammonium sulphate, $Al_2(SO_4)_3(NH_4)_2SO_4 + 24\,Aq$.

Sometimes alum is added to turbid or polluted waters: a flocculent precipitate is formed which carries down with it many bacteria and renders the water clearer and purer.

9. *Carbon dioxide may be generated in nature* by: (1) Respiration of men and animals; (2) combustion of fuel; (3) fermentation.

10. The *chemical name* of tartar emetic is antimonyl potassium tartrate. *Poisonous effects:* Nausea, vomiting, burning pain in esophagus and stomach, intense thirst, pain on swallowing, purging, pulse first quick, then slow and

weak, skin cold and moist, cramps in extremities, vertigo, syncope, loss of consciousness, and collapse. *Antidote* Tannin, or tincture of cinchona.

DIAGNOSIS.

1. *Reduplication of heart-sounds.* "The normal heart sounds consist of two systolic and two diastolic sounds so blended as to form one systolic and one diastolic tone because of the synchronous closure of the valves of the right and left heart. Under many conditions this synchronism is so interfered with as to produce doubling or actual division of one or both sounds. The phenomenon of reduplication has aptly been compared to the sound produced by the closure of double swinging doors. A normal heart, if temporarily overacting, may be the seat of doubling or splitting of the heart sounds; but in general it may be said that, hearing a reduplicated second sound or triple rhythm at the apex, one should suspect the presence of mitral stenosis or myocardial degeneration. *Gallop rhythm* is a form of reduplication heard over the whole heart, though sometimes more plainly over one side that may be graphically represented. It is usually strongly suggestive of marked incompensation, interstitial nephritis, emphysema, arteriosclerosis, and exophthalmic goiter."—(Greene's *Medical Diagnosis.*)

2. *Mitral systolic murmurs* may indicate: Mitral regurgitation; acute endocarditis; anemia (or chlorosis); an acute infectious disease, in children; or, in infants, a patent ductus arteriosus.

3. *Arrhythmia* occurs when the normal rhythm of the pulse is disturbed. There are five chief varieties: "(1) The *intermittent pulse* may be observed as the result of excessive eating, the habitual use of tobacco, coffee, and tea, exercise, mental excitement, myocardial disease, and reflex irritation such as produced by constipation, dyspepsia, lithemia, hypochondriasis, etc. (2) The *irregular pulse* may be due to the same causes as the preceding. As a pathological condition it is most often encountered in organic cardiac disease, especially that which gives rise to mitral regurgitation. (3) The *dicrotic pulse* is one in which the first impulse is quickly followed by another impulse or secondary wave. It owes its production largely to conditions which relax the arterial walls and lower the tension, especially adynamic affections such as typhoid fever. (4) *Pulsus paradoxus* is that condition of the pulse in which the pulse-wave becomes small and feeble during inspiration; it may occur in health but is rather common as the result of pericardial adhesions. *Water-hammer* or *Corrigan's pulse* is that pulse which is characterized by a short, sharp, strong impulse which seems to collapse under the examiner's fingers. It is best detected by holding the arm up, and is diagnostic of aortic regurgitation during compensation."—(Hughes' *Practice of Medicine.*)

4. *"Dyspnea may be due* to obstruction of the air passages, pressure upon the respiratory system from without by tumors, and distention of abdomen, diseases of the lungs and pleura, heart disease, asthma, anemia, or paralysis of muscles of respiration as the result of hemorrhage, tumors, or degeneration of the respiratory center in the medulla or toxic agents in the blood. It may be *inspiratory* when it results from obstruction, as in foreign bodies in the larynx or trachea, or it may be *expiratory*, as in emphysema or bronchial asthma. A combination is the more frequent condition. In all forms of dyspnea it is important to determine whether the shortness of breath bears any relation to exertion. Dyspnea *independent of exertion* is a serious condition and is symptomatic of severe cardiac and pulmonary disease. Dyspnea *dependent upon exertion* is less serious and is observed in health, simply debility, anemia, obesity, and somewhat moderate cardiac debility."—(Hughes' *Practice of Medicine.*)

5. *Decreased resonance on percussion* may be found in: Phthisis, pneumonia, pleural effusion, and hydrothorax. Areas of consolidation, especially near the surface of the lung, yield a marked dullness.

6. Diplopia (unless due to the action of alcohol or a few drugs) indicates paralysis of the ocular muscles.

7. *The liver is generally found enlarged* in: Passive congestion (usually from valvular cardiac disease), amyloid disease, cancer, fatty infiltration, hypertrophic cirrhosis, leucemia, hydatids, abscess, or gumma.—(Butler's *Diagnostics of Internal Medicine.*)

8. The knee-jerk is exaggerated when the inhibitory fibers from the cerebrum are cut off. This may occur in: Cortical hemiplegias, lateral or amyotrophic sclerosis of the cord, hysteria, neurasthenia, tetanus, or strychnine poisoning.

9. *Abnormal constituents of the stools* may be: Undigested food, blood, mucus, pus, fat, calculi, intestinal parasites, foreign bodies, and fragments of tumors.

Undigested food may indicate: Diarrhea, overfeeding, dyspepsia. *Blood*: Hemorrhage, ulcer, or cancer in stomach, intestines, or liver; fissures, hemorrhoids, portal obstruction, intussusception, acute yellow atrophy of the liver, typhoid. *Mucus:* Intestinal catarrh, inflammation of intestines, dysentery. *Pus:* Rupture of an abscess into the alimentary canal, dysentery, ulceration of intestines. *Fat:* Cancer, or inflammation of pancreas, impaction of pancreatic duct. *Calculi:* Gallstones. *Intestinal parasites:* Worms, etc.

10. See French's "Practice of Medicine" (1910), page 1052; or Osler's "Practice of Medicine" (1909), page 1034.

PATHOLOGY.

1. See French's "Practice of Medicine" (1910), page 735, or Osler's "Practice of Medicine" (1909), page 445.

2. *The chief changes that take place in senility:* Cessation of growth; loss of weight; loss of stature; brittleness of bones; rigidity of cartilages; loss of elasticity of crystalline lens; feebleness and atrophy of muscles; grayness of hair; diminution of sexual activity and power; arteriosclerosis, or other diseased conditions of the arteries; lessened capacity of chest; atrophy and degeneration of digestive glands, kidneys, and testicles or ovaries; slowed reflexes; impairment of the special senses.

3. See French's "Practice of Medicine" (1910), page 807; or Osler's "Practice of Medicine" (1909), page 513.

4. The basis of the opsonic treatment is the belief that the leucocytes can be aided in their work of phagocytosis or bacteriolysis if a certain substance is added to the blood-serum.

The effect of an injection of bacterial vaccine is: Rise of temperature, pain in joints, an urticarial or erythematous rash, itching, chill, giddiness, faintness, vomiting, heart-failure, collapse, convulsions, coma.

5. See French's "Practice of Medicine" (1910), page 1082; or Osler's "Practice of Medicine" (1909), page 887.

6. *Paths of bacterial infection:* Through abraided skin or mucous membrane; through mucous membrane of digestive, respiratory, or genitourinary tract; through conjunctiva.

Paths of extension: By continuity of tissue, by blood current, by lymphatics, by reinfection, or by mechanical conveyance from one place to another.

7. See Rose and Carless' "Surgery" (1911), page 678; or Da Costa's "Surgery" (1908), page 552.

8. An *antitoxin* consists of a product of bacteria, but not the bacteria themselves; whereas a *bacterial vaccine* is a preparation of killed bacteria.

9. See French's "Practice of Medicine" (1910), pge 687; or Osler's "Practice of Medicine" (1909), page 622.

10. *Some of the adulterations found in foods are:* Alum, copper, lead, lime, iron, turpentine, water, anilin colors, pepper, essences, gypsum, starch, burnt sugar, flour, potatoes, oleomargarine, chicory, acorns, turmeric, glucose, gelatin, salt, grit, sand, pollen, dirt, acids, leaves. For *detection* see some good book devoted to the subject.

PRACTICE.

1. See French's "Practice of Medicine" (1910), page 974; or Osler's "Practice of Medicine" (1909), page 420.

2. See French's "Practice of Medicine" (1910), pages 910, 912, and 915; or Osler's "Practice of Medicine" (1909), pages 686, 688, and 690.

3. See French's "Practice of Medicine" (1910), pages 1068 and 1070; or Osler's "Practice of Medicine" (1909), pages 915 and 917.

4. See French's "Practice of Medicine" (1910), pages 568 and 573; or Osler's "Practice of Medicine" (1909), pages 775 to 783.

5. See French's "Practice of Medicine" (1910), pages 222, 225, 226, and 230; or Osler's "Practice of Medicine" (1909), pages 219, 221, 223, and 226.

6. See French's "Practice of Medicine" (1910), pages 218, 219, and 221; or Osler's "Practice of Medicine" (1909), pages 210, 211, and 213.

7. See French's "Practice of Medicine" (1910), pages 360 and 306.

8. See French's "Practice of Medicine" (1910), pages 646 and 649; or Osler's "Practice of Medicine" (1909), pages 857 and 860.

9. See French's "Practice of Medicine" (1910), pages 132 and 137; or Osler's "Practice of Medicine" (1909), pages 152 and 155.

9. See French's "Practice of Medicine" (1910), page 800; or Osler's "Practice of Medicine" (1909), pages 507, 511, and 500.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 319; or Hirst's "Obstetrics" (1909), page 141.

2. Symptoms of death of fetus are: cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements are absent, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time crepitus of its cranial bones may be elicited.

3. See Williams' "Obstetrics" (1909), page 807; or Hirst's "Obstetrics" (1909), page 584.

4. *The different displacements of the uterus* are: Retroversion, retroflexion, anteversion, anteflexion, lateral version, lateral flexion, descent, prolapse, ascent, and malocation (to front, back, or one side).

General treatment consists in: Removal of cause (when possible), reposition, retaining in position by tampons or pessaries, breaking up of adhesions, various operations (according to the conditions present).

5. CYSTITIS. *Symptoms:* Frequent urination, with tenesmus and a burning sensation in the urethra; later on pain in the bladder, hematuria, and the urine contains pus and epithelial cells. Chills, rapid pulse, fever, and headache may also be present. *Treatment:* Rest in bed; the imbibition of plenty of milk and water, and the avoidance of all highly seasoned food; laxatives; diuretics; sitz bath; irrigation of the bladder with an antiseptic solution; hot fomentation and vaginal douches are often helpful; sometimes intravesical medication is necessary.

6. See Williams' "Obstetrics" (1909), page 813; or Hirst's "Obstetrics" (1909), pages 575 and 577.

7. See Williams' "Obstetrics" (1909), pages 151 and 211; or Hirst's "Obstetrics" (1909), pages 92 and 395.

8. See Williams' "Obstetrics" (1909), page 280; or Hirst's "Obstetrics" (1909), page 425.

9. See Williams' "Obstetrics" (1909), pages 525 and 541; or Hirst's "Obstetrics" (1909), pages 630 and 635.

10. See Williams' "Obstetrics" (1909), pages 110, 128, 132, and 156; or Hirst's "Obstetrics" (1909), pages 143, 120, and 125.

SURGERY.

1. *Treatment of tuberculous sinuses:* "The treatment varies with the conditions present, and must include measures directed to the lesion from which the sinuses have originated. The extent and direction of any given sinus may be demonstrated by the use of the probe, or, more accurately, by injecting the sinus with a paste of bismuth and vaseline—subnitrate of bismuth, 30 parts; white vaseline, 60 parts; soft paraffin, 5 parts; wax, 5 parts—and following its track in an *x*-ray photograph. It has been found by Beck of Chicago that the injection of bismuth paste is frequently followed by healing of the sinus, and that, if one injection fails to bring about a cure, repeating the injections every second day may be successful. Iodoform suspended in glycerin may be employed in a similar manner. When these and other non-operative measures fail and the whole track of the sinus is accessible it should be laid open, scraped, and packed with gauze until it heals from the bottom."—(Thomson and Miles' *Manual of Surgery.*)

2. *Hypodermoclysis* is the subcutaneous injection of saline infusion. And see Rose and Carless' "Surgery" (1911), pages 280 and 278; or Da Costa's "Surgery" (1908), pages 243 and 242.

3. See Rose and Carless' "Surgery" (1911), pages 678 and 684; or Da Costa's "Surgery" (1908), pages 552 and 556.

4. See Rose and Carless' "Surgery" (1911), page 812; or Da Costa's "Surgery" (1908), pages 765 and 142.

5. See Rose and Carless' "Surgery" (1911), page 1161; or Da Costa's "Surgery" (1908), page 1014.

6. See French's "Practice of Medicine" (1910), page 572; and Rose and Carless' "Surgery" (1911), page 939; or Da Costa's "Surgery" (1908), pages 395 and 348.

7. The *indications* for ligating the internal carotid artery are wounds and aneurysm. Special care must be taken when opening the sheath to avoid wounding the internal jugular vein, vagus, and cervical sympathetic nerves, and ascending pharyngeal artery. The needle should be passed from the side of the internal jugular and the pneumogastric. For description of the operation see Rose and Carless' "Surgery" (1911), page 331; or Da Costa's "Surgery" (1908), page 416.

8. "*Plastic surgery* includes operations for the repair of deficiencies, for the replacement of lost parts, for the restoration of function in parts tied down by scars, and for the correction of disfiguring projections. Many reparative operations have been devised. Among them are: cheiloplasty, or the construction of a new lip; the closure of a cleft in the palate, the lip, or the penis; the making of a new nose; skin-grafting, grafting of muscle or tendon; nerve-grafting; the introduction of celluloid or metal into the tissues to act as supports; the injection of paraffin into the tissues to amend a depression; the diminution in the size of a lip or a nose; the amendment of protuberant ears; the correction of distortion due to cicatrices; excision of scars; closure of congenital sinuses and of fistulæ; removal of disfiguring growths."—(Da Costa's *Surgery.*)

9. See Rose and Carless' "Surgery" (1911), page 80; or Da Costa's "Surgery" (1908), page 196.

10. See Rose and Carless' "Surgery" (1911), pages 226 and 1068; or Da Costa's "Surgery" (1908), page 343.

DERMATOLOGY, SYPHILOLOGY, AND DISEASES OF THE EYE, EAR, NOSE, AND THROAT.

1. *Tinea trichophytina* is a contagious parasitic affection characterized by the development of circumscribed patches or rings. It is also called *ringworm*. *Varieties:* Tinea trichophytina capitis, barbæ, corporis, unguium. *Treatment:* Washing, epilation (if on a hairy part), and the use of parasiticide applications.

2. *Psoriasis* is a common chronic inflammatory disease of the skin, characterized by variously sized lesions, having red bases covered with white scales resembling mother-of-pearl. It affects by preference the extensor surface of the body. The lesions are infiltrated, elevated, clearly defined, covered with white, shining, easily detachable scales which, upon removal, reveal a red, punctuate, bleeding surface. The eruption is absolutely dry, and itching is usually absent.

PSORIASIS.	ECZEMA SQUAMOSUM.
1. Predilection for elbows, knees, and scalp.	1. No seat of predilection.
2. Patches small, round, and sharply marginated.	2. Patches large, irregular, and ill defined.
3. Scales abundant, firmly attached, and mother-of-pearl in color.	3. Scales scanty, loosely attached, and grayish or yellowish in color.
4. Moisture never present.	4. Often history of antecedent moisture.
5. Itching slight, often absent.	5. Itching marked.
6. Disease often lasts with recurrent attacks throughout a lifetime.	6. More amenable to treatment.

(Schamberg.)

3. *Eczema* is an acute, subacute, or chronic, noncontagious inflammatory disease of the skin, characterized primarily by erythema, vesicles, papules, or pustules, and, secondarily, by scales and crusts, and accompanied by itching and burning. The various forms of eczema constitute about thirty per cent. of all skin diseases. There are several varieties corresponding to the most predominant lesion. These may continue as such or terminate in eczema rubrum or eczema squamosum. The diagnosis of eczema is, as a rule, easy. The most distinctive features are: (1) Serous exudation; (2) the gradual merging of the patches into the surrounding healthy skin; (3) polymorphism of the lesions; (4) the symmetry of the eruption; (5) the marked itching and burning.

ERYSIPELAS.	ECZEMA ERYTHEMATOSUM.
1. Sudden onset with chill and marked constitutional symptoms.	1. No constitutional symptoms.
2. Eruption sharply marginated.	2. Fades into surrounding skin.
3. Glazed, shining surface; great edema.	3. Dull, scaly surface; slight infiltration.
4. Color violaceous.	4. Color bright or dull red.
5. Burning pain.	5. Itching more marked.
6. Occurrence of discrete vesicles or blebs.	6. Vesicles occur in patches if at all.
7. Progressive peripheral spreading.	7. Spreading irregular.
8. Runs an acute course.	8. Runs a chronic course.
9. Contagious.	9. Not contagious.

(Schamberg.)

4. The initial lesion of syphilis is the chancre.

5. See Rose and Carless' "Surgery" (1911), page 149; or Da Costa's "Surgery" (1908), page 282.

6. *Astigmatism* is an error of refraction caused by some irregularity of the curvature of the refracting surfaces of the eye.

Causes. "Astigmatism is usually due to a change in the curvature of the cornea, with or without some shortening or lengthening of the antero-posterior diameter of the eyeball. It is also caused, in part at least, by defects in the curvature of the lens; this lenticular astigmatism may partly neutralize that of the cornea. It is usually congenital and there is often an hereditary tendency. It may, however, be acquired, and is then caused by corneal changes resulting from inflammation, injury, or operation. Pressure of the lids in ametropia is sometimes considered a factor in acquired regular astigmatism." (May.)

Astigmatism is corrected by cylinders, sphero-cylinders, or crossed cylinders. The curve of the corresponding cylinder corresponds to the ametropic meridian; consequently its axis is at right angles to this meridian.

7. "*Plastic iritis.* An inflammation of the iris in which a scant, fibrinous exudate is deposited on the anterior or posterior surface of the iris, the pigment layer at the edge of the pupil thereby becoming adherent in places to the capsule of the lens. The symptoms are intense pain in the forehead and face, lacrimation, photophobia, dimness of vision, pericorneal injection, loss of luster of the iris, and hazy, distorted, and immobile pupil. The course of the disease is from 2 to 4 weeks. Synechiæ often result. It is due to exposure to cold, syphilis, tuberculosis, rheumatism, etc., but may be secondary to other ocular inflammation, traumatism, foreign body, etc. The original cause should be treated by the administration of the iodides, salicylates, mercurials, etc. The instillation of atropine, dark glasses, and, if pain is severe, hot compresses, leeches to the temple, and morphine should be prescribed. The diet should be liquid. Puncture of the cornea to relieve tension may be necessary."

"*Serous Iritis.*—A chronic inflammation in which an inflammatory product, poor in cells, settles in the anterior chamber, causing a haziness of the aqueous, and deposits on the posterior surface of the cornea. Opacities on the posterior portion of the cornea and vitreous and lenticular opacities and posterior synechiæ often follow. This condition results from debility, anæmia, syphilis, etc., and may follow cataract operations. In addition to constitutional treatment, atropine should be instilled twice daily, and sometimes paracentesis and iridectomy may be indicated. Heat, diaphoresis, and the iodides will aid in the absorption of the exudate.

"*Suppurative Iritis.*—A rare condition in which the inflammatory product is purulent and saturates the tissues of the iris and overflows into the anterior chamber, forming a hypopyon. It results from infection or diabetes."

Obstetrical Anatomy of Double Congenital Luxation of the Hip Joints with Reference to the Pelvis.—J. Dalmas has made a study of the pelvis of women who suffer from double congenital luxation of the hip. He concludes that the pelvis in these cases is not a contracted one, the only contraction being found in the large pelvis, due to drawing together of the wings of the os innominatum. The superior and inferior straits and the cavity are all generally increased. They are found decreased only in cases in which there is a general atrophy of the entire pelvis. The pelvis is markedly anteverted and there is a marked lordosis of the spine.—*L'Obstetrique.*

Tracheobronchial Adenopathies in Children.—H. Grenet considers the study of tracheobronchial enlarged glands of great importance. They are always present in young tuberculous subjects and are not easy to diagnose. There are other forms of infectious adenitis that are not tuberculous. All pulmonary affections are accompanied by enlarged tracheobronchial glands. These may be secondarily invaded by the tubercle bacillus. Typhoid fever, mumps, and various infections of adenoid growths and tonsils also produce enlarged glands. They are found in hereditary syphilis and in leucemia. Tuberculosis is the main cause of tracheobronchial adenopathy, which is never absent in tuberculosis of childhood. It is also found in nursing infants. They are occasionally infected from the intestines, although more rarely than from above. Tracheobronchial adenopathy, although secondary, constitutes almost the only focus for bacilli and may be the point of departure for pulmonary or generalized tuberculosis.—*Annales de Médecine et Chirurgie Infantiles.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

MEINE PRAPARATIONSMETHODE DES OPERATIONSFELDESMITTELS JODTINKTUR. By Dr. ANTONIO GROSSICH. 80 pages; paper; price 75 cents. Rebman Company, Publishers, New York.

SERUM DIAGNOSIS OF SYPHILIS AND THE BUTYRIC ACID TEST FOR SYPHILIS. By HIDEYO NOGUCHI. 238 pages; illustrated; cloth; price $2.50. J. B. Lippincott Company, Publishers, Philadelphia.

TEXT-BOOK OF OPHTHALMOLOGY. By Dr. ERNST FUCHS; translated by ALEXANDER DUANE, M.D. Fourth Edition. 980 pages; with 441 illustrations; cloth; price $6.00. J. B. Lippincott Co., Publishers, Philadelphia.

LA FATIGUE ET LE REPOS. By Dr. FERNAND LAGRANGE. 300 pages; paper; price 6 francs. Librairie Felix Alcan, Publishers, Paris.

TRANSACTIONS OF THE AMERICAN OTOLOGICAL SOCIETY. Vol. XII. Part II. Forty-fourth Annual Meeting, Hotel Chelsea, Atlantic City, N. J., June 20 and 27, 1911. 466 pages; paper. Published by the American Otological Society.

THE OPHTHALMIC YEAR BOOK. Vol. VIII. By EDW. JACKSON, M.D., THEO. S. SCHNEIDEMAN, M.D., and WM. ZENTMAYER, M.D. 455 pages; illustrated; cloth. The Herrick Book & Stationery Co., Publishers, Denver, Colo.

MINOR SURGERY. By LEONARD A. BIDWELL, F.R.C.S. 265 pages, with 88 illustrations; cloth. Published for the Univ. of London Press by Hodder & Stoughton and Henry Frowde.

ANÆSTHESIA AND ANALGESIA. By J. D. MORTIMER, M.B., F.R.C.S. 276 pages; illustrated; cloth. Published for the Univ. of London Press by Hodder & Stoughton and Henry Frowde.

LEITFADEN DER ELEKTRODIAGNOSTIK UND ELEKTROTHERAPIE. By Dr. TOBY COHN. 212 pages; illustrated; paper; price 6.60 M. S. Karger, Publisher, Berlin.

DIE STÖRUNGEN DES VERDAUUNGSAPPARATES ALS URSACHE UND FOLGE ANDERER ERKRANKUNGEN. Part I. By Dr. HANS HERZ. 218 pages; illustrated; paper; price 6 M. S. Karger, Publisher, Berlin.

DIE STÖRUNGEN DES FARBENSINNES IHRE KLINISCHE BEDEUTUNG UND IHRE DIAGNOSE. By Dr. HANS KOLLNER. 428 pages; illustrated; paper; price 14 M. S. Karger, Publisher, Berlin.

HAYDEN'S EXAMINING AND OPERATING AERO-URETHROSCOPE

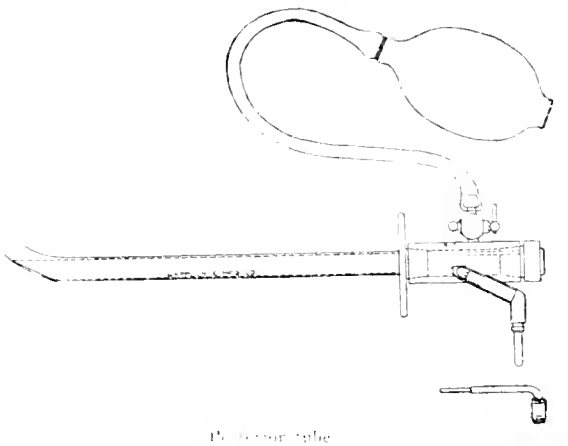
By JAMES R. HAYDEN, M.D.

NEW YORK.

[illegible] GENITO-URINARY DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS (COLUMBIA UNIVERSITY); ATTENDING GENITO-URINARY SURGEON, BELLEVUE HOSPITAL.

In the present type of urethroscopes, with either direct or indirect illumination, there are several practical objections: (1) The difficulty of making applications, or of operating on the urethra under direct and unobstructed inspection. (2) The canal cannot be dilated with air, which is most essential in some pathological conditions. (3) The lamp in the direct form obscures the field more or less and if smeared with blood or secretions gives no light.

To obviate these objections and to supply an instrument with unobstructed field, in which the operator can see the lesions while treating them, I have devised the present urethroscope, which can be used either in the anterior or posterior urethra, and even in the bladder, where the ureteral orifices can be found and catheterized, small stones or foreign bodies removed, and the mucous membrane clearly seen. The tubes for the anterior urethra are 5



Posterior tube.

inches long and those for the posterior urethra 6¾ inches, but can be lengthened or shortened according to the requirements of the case, and made in any caliber. The proximal ends of the obturators and tubes are *milled* so as to give the operator a firm hold, and *flattened* above and below to prevent their rolling when laid down. The little lamp consists of a carbon filament in front of which is a planoconvex "collecting" lens, which gathers and projects the rays to the distal end of the tube where the field is seen in brilliant illumination. The lamp is held in a metal collar *outside* of the tube so that it does not encroach on the field, is not in the way of applicators, examining or operating instruments, and cannot be soiled and obscured by blood, secretions, or the lubricant. If *air distention* is required, an air tight cap with magnifying lens is slipped over the proximal end of the collar and the urethra *easily* and *carefully* dilated by *slowly* compressing the little bulb which forces air down the tube, where it can be retained by shutting off the stop cock. Water distention may also be used, if so desired. For simple examination, treatment, "fulguration" or the "ultra-violet ray," a magnifying lens is attached to the collar by a slender rod which allows of the use of applicators and any kind of instruments under direct visual inspection.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended January 6, 1912.

	Cases	Deaths
Tuberculosis Pulmonalis	396	167
Diphtheria	264	20
Measles	505	7
Scarlet Fever	239	8
Smallpox		
Varicella	173	—
Typhoid Fever	65	11
Whooping Cough	22	3
Cerebrospinal Meningitis	3	3
Malarial Fever	—	—
Totals	1,667	219

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended January 5, 1912.

Places	Date	Cases	Deaths
CHOLERA			
Bulgaria: Varna	Nov. 6	1	
Dutch East Indies			
Total Sept. 24-Oct. 9, 1911: Cases, 322; deaths, 256

SOME EXTRAPULMONARY SOUNDS WHICH SIMULATE RALES.

By GEORGE E. BUSHNELL,

COLONEL MEDICAL DEPARTMENT, U. S. ARMY.

THE fact that sounds of various origin which imitate râles may be obtained by auscultation over the normal thorax has not received the attention that its importance in diagnosis warrants. The study of these sounds is of special interest in examinations for early pulmonary tuberculosis in which weighty diagnoses are frequently based upon scanty auscultatory phenomena.

1. The sounds produced by the contraction of muscles, especially of the trapezius, are well known. The hum of contracted muscular fiber is not only confusing but the tension of which it is a sign interferes with a free respiration in the apices. It may be difficult to be certain that the enfeeblement and the apparent change of character of the respiratory sounds resulting from the tension of the muscles are not due in part to pulmonary conditions. It has been found that in peculiarly difficult cases it is of advantage to cause the subject to recline prone upon a high couch, first one and then the other arm being allowed to dangle over the edge while the back is under examination. This position will often be found to relax the offending muscles completely. Muscular contractions do not often simulate râles so perfectly as to mislead an examiner of any experience, although the writer has known the mistake to be made when the muscular contractions were localized over a small area.

2. Marginal sounds are crepitations which are heard during inspiration over the base of the lungs and are not associated with other evidences of organic disease of this portion of the lung.

According to Von den Velden[1], sounds occurring in the lung margins have been mentioned by writers since the middle of the 19th century. They have been interpreted by some as pneumonic or bronchiolitic râles or pleural rubbings, and by others as due to atelectasis. Others still have not attempted an explanation, and a few have apparently regarded them as so-called accidental or external sounds. Rosenbach[2],[3],[4], in an article upon pseudo-pulmonary and pseudo-pleural sounds, calls attention to the muscle sounds over the apices and states that a modification of the same sound is observed on auscultation and palpation over the lower and lateral parts of the thorax, especially in the axilla between the sixth and tenth intercostal spaces. They are found, he says, especially in individuals with broad intercostal spaces and considerable mobility of the lower edge of the lung. The creaking (Knarren) which represents exactly the type of the new leather sound is not only audible, but in some cases palpable. In other cases the sound is still perceptible by palpation but differs from the leather sound of pleurisy. The audible and palpable creaking is regarded by him as arising in the intercostal muscles. It is the plainer, he says, the greater the extension of the muscle, and is therefore heard best in young individuals who breathe vigorously, but is also found in older dyspneics and in emphysema. It is distinguished from pleural friction sounds by the fact that it appears symmetrically, is surprisingly constant, and occurs in the absence of other symptoms of disease.

Burghart[5] discovers râles at the base of the lung at a point between the mammillary and anterior axillary lines "in even trivial catarrhs of the apices." These râles are for him pathological, and according to his theory are due to the presence of bronchial secretion which has been aspirated from the diseased focus. The râles, he says, differ in quality according to the nature of the aspirated secretion and the length of time during which it has lain in the lower margin of the lung, being usually fine, dry crepitating, but sometimes coarser and moister. The râles are always heard on the diseased side. If they are heard on the other side it appears later that this side is also affected. The râles are interpreted by him as an early sign of apical tuberculosis. The sounds under consideration are sometimes known as the marginal sounds of Burghart. This name should not, however, be given to them even if the pathological significance ascribed by Burghart to them is accepted, for Burghart was not the first to express this view. According to Wintrich (cited by Von den Velden) Walshe enunciated it in 1851. Kuhn[6], discussing "Burghart's symptom," approves of Burghart's explanation for some cases, but says that in others the crepitations are so extraordinarily fine and so similar to the sound caused by entrance of air into atelectatic tissue that they could hardly be explained by the presence of a collection of fluid. He considers slight moist, or dry, pleurisy to be the causal condition, rejecting atelectasis on account of the persistence of the sounds, since in true atelectasis the sound would be heard but once. In support of the pleurisy theory he brings forward the fact that the presence of fine crepitations in exudative pleurisy has been mentioned by Strümpell, Fardieu, Rothbach, and especially Janowski[7], who reports hearing in even slight cases of pleurisy fine râles resembling the so-called crepitatio redux of the last stage of pneumonia, the diagnosis being established in some cases by the subsequent removal of fluid by aspiration, after which the sounds disappeared. Janowski explains these sounds by the pressure of pleural fluid by which the agglutination of single pulmonary vesicles is effected, *i. e.* by what might be called a disseminated atelectasis. Kuhn assumes a dry pleurisy for less "moist" crepitations,

which he says are of course to be heard also on expiration, although he does not state whether their presence in expiration is assumed by him on theoretical grounds purely, or has been determined by actual observation. Von den Velden[1] recognizes the presence of marginal sounds in healthy lungs. According to him they disappear almost always after 12 to 15 breaths; are especially frequent in women, even in young women; are also met with in older corpulent men of a sedentary mode of life, but almost never in young men. He considers them due to a pure uncomplicated form of marginal atelectasis, the cause of which is to be sought in diminished activity of the diaphragm or "in inability to use the ribs in the usual way in inspiration." He finds the sounds present also in apical tuberculosis, more frequently and at an earlier time upon the affected side. In this condition also he considers the sounds to be due to a pure marginal atelectasis, at least in the beginning, the atelectasis being caused by a diminished activity of the diaphragm. Wilson[2] mentions crepitant râles sometimes associated with subcrepitant râles as being frequently present during deep inspiration at the bases of the chest posteriorly and laterally in persons whose respiration is habitually shallow, not only in the case of the bedridden, but also in many healthy persons, especially after middle age.

Sahli[3] refers to the marginal sounds as physiological crepitant râles. They are due, in his view, to the fact that "when there is little need of air the lungs are not freely expanded so that the alveoli at the borders of the lung may become empty through compression. If then the patient be made to take several full breaths the air rushing into the collapsed alveoli may cause crepitation. These physiological crepitations usually occur symmetrically on both sides, especially in front, and disappear after a few breaths." The American editors of Sahli refer to what are apparently the same sounds as subcrepitant râles resembling friction sounds in the lower axillary region of apparently normal individuals, and cite, with approval, Cabot's view that they are to be attributed to a partial atelectasis resulting from disuse of the thin pulmonary margins. Cabot[10] speaks of the sounds as crepitant and subcrepitant râles heard along the thin margins of the lungs at the base of the axillæ and in the back. They are sometimes transitory, disappearing after a few deep breaths have been taken by an individual who had previously been breathing superficially. In other cases they persist despite deep breathing. Cabot found the marginal sounds present in 228, or 61 per cent. of 356 normal chests. They are rarely to be heard in persons under 20. After 45, on the other hand, he says it is unusual not to find them. Cabot's conclusions are that we must recognize the fact that "it is almost or quite physiological" to find the finer varieties of crackling râles at the base of the axillæ in persons over 40 years of age. Cabot refers to these sounds as disappearing after a few deep breaths in most cases, but sometimes as "audible as long as we choose to listen to them."

Rosenbach is undoubtedly correct in ascribing the "sound of new leather" to the contraction of the intercostal muscles. It is heard best, as he says, in young individuals who breathe vigorously. The sound of muscular contractions, which, to the writer's ear, is softer than the leather sound of pleurisy, may be heard during vigorous inspiration, but is not conspicuous and is usually absent. Its character should not lead to confusion with intrathoracic sounds. If Rosenbach had described more distinctly the sound which he says differs from "the leather sound of pleurisy" he might be credited with being the first to assert that the marginal sounds are physiological. At all events the credit is due him of having indicated the correct method of investigation, the examination of healthy individuals for the presence of a phenomenon before it is decided to be of a pathological nature.

Burghart's view that the marginal sounds are due to the aspiration of mucus from an apical lesion is inherently improbable. Such aspiration would not be confined to the lower margin but would involve the entire lower lobe, in which case sounds heard would not be limited to the margins of the lungs as is the case with the marginal sounds.

The theory of Kuhn that the sounds are due to a dry pleurisy has had many unconscious supporters, for "dry pleurisy at the base" figures in many diagnoses of lesions of the upper lobe, and marginal sounds are, perhaps, responsible for more errors than any other auscultatory phenomenon. Crepitations due to dry pleurisy and also to pleurisy with effusion, as especially described by Janowski, no doubt occur at the base of the lung and are to be distinguished from marginal sounds. The modern tendency is to refer the marginal sounds to an atelectasis or to a condition approaching atelectasis due to deficient expansion of the thin margin of the lung.

Atelectasis, according to Fraenkel[11], is most frequently met with in the edges of the lungs, especially of the lower lobe, but true atelectasis is due to definite intrathoracic disease, pleurisy, pneumothorax, the plugging of a bronchus with secretion, etc., or if due to compression exerted through the diaphragm, as from meteorism, abdominal tumors, liver abscess, the pressure must be sufficiently great to crowd up the diaphragm beyond its expiratory position. A sedentary life, obesity, advancing years, etc., are quite insufficient causes of atelectasis in the absence of pulmonary or abdominal disease. Cabot[10] attempts to prove that the marginal sounds are due to atelectasis by showing that after a few full breaths the lungs will be found to extend downward nearly an inch beyond their former level. This he explains by the distention of previously collapsed air vesicles. The phenomenon is well known but is usually interpreted differently. Hofbauer and Holzknecht[12] state that "in almost all cases inspiration alone is deepened in deep breathing, the expiration not increasing in strength. The reason of this is that the inspiration is produced by muscular action and so is capable of increase, whereas the expiration cannot be increased because it depends upon the elasticity of the lung. The auxiliary muscles of expiration are not generally called into play, for this would mean the resort to a mechanism foreign to ordinary respiration. There develops, therefore, even under physiological conditions, a distention of the lung during deep breathing."

The descent of the diaphragm is due to a distention of the lung above its usual size, not to a return to normal after collapse, the proof of which is that the lung returns gradually to its former level after the cessation of deep breathing, the phenomenon being met with in the robust, in which there can properly be no thought of a collapsed condition of the bases of the lungs sufficient to account for the change in level. It must be remembered that, while the base of the lung is undoubtedly especially exposed to compression through the diaphragm, in compensation for this it is directly subject to the

influence of the most powerful and freely movable parts of the respiratory apparatus, the diaphragm and the lower thorax. Compression (or relaxation) of this part of the lungs sufficient to cause atelectasis could not, therefore, be anticipated except in the presence of well-marked pathological conditions.

A massive atelectasis of the pulmonary margin is then out of the question in the etiology of the marginal sounds. If by a partial or incomplete atelectasis is meant the presence of atelectatic cells, or groups of cells among expanded cells, it need only be said that such a supposition is not warranted by the mode of production of atelectasis (Lichtheim[2]). With regard to Cabot's hypothesis that the marginal sounds are produced by the separation of agglutinated walls of bronchioles partially collapsed by compression or disuse, one cannot, of course, disprove the possibility of such partial collapse under some conditions, but the explanation does not fit with the observed facts concerning marginal sounds. It might, perhaps, pass in the case of the tuberculous apex, but it is impossible to believe that in the average healthy individual the most strongly breathing portion of the lung is in a condition of partial collapse during rest, and if we adopt this hypothesis to explain the continuance of marginal sounds in the athlete we would be obliged to suppose that the lung margins are compressed during each expiration sufficiently to bring the walls of the bronchioles into contact, a most improbable assumption. In the expiratory ascent of the lung its retraction occurs not only vertically upward, but also, on account of the shape of the thorax, necessarily inward. We cannot conceive of the lung margin as being, as it were, pinched between the ascending diaphragm and the ribs in such a way as to be subjected to actual compression.

Several writers have pointed out that the marginal sounds are found in a considerable percentage of healthy persons, but we cannot accept the limitations as to the prevalence of these sounds which are set by them. The marginal sounds are heard in children and in young men as well as in young women. They are found in individuals who are sedentary, obese, advancing in years. They are also heard in young athletes. Dr. E. H. Bruns has found them in a young man who was training for a prize fight. They are heard on the affected side in apical tuberculosis. They are also to be found on the healthy side in the same case. The marginal sounds, in short, are a purely physiological phenomenon. The usual transitoriness of the sounds is the cause of their ascription to atelectasis. The real reason why they are transitory is that, as already indicated, the average individual when breathing deeply inspires more strongly than he expires, with the result that after a few inspirations he is no longer able to breathe as vigorously as is necessary for the production of the sounds. If expiration equals inspiration the sounds are producible until the subject is exhausted. To balance expiration with deep inspiration is only possible by bringing into action the expiratory muscles. To do this some instruction is generally requisite. In studying the marginal sounds select a young man with a well developed chest, a man of athletic training is to be preferred. After a little instruction in forced expiration, mark in the axilla (the right axilla is preferable) the level of the base of the lung on full inspiration and on forced expiration. The latter line will be found at, or a little above, the level of the nipple. The inspiratory line will be from 3½ to 4½ inches below this in the anterior axillary line in good breathers. Cause the subject to empty his lungs as completely as possible, and then take a full breath. The inspiration should be strong and full, but not extremely rapid. Its duration should be from 1 to 2 seconds. Auscultation of the thorax between the two lines, if the breathing is properly performed, reveals the presence of a shower of crackles, sounds resembling crepitant râles but not quite so fine. The sounds are heard only during inspiration and may be obtained anywhere in the region indicated. They are not, however, obtained synchronously over this surface, as is shown by the following experiment. Let two examiners apply their stethoscopes simultaneously, the one a little below the expiratory line, the other a little above the inspiratory line. During inspiration each examiner denotes by some sign the instant when he first hears the marginal sounds. It will be found that the sounds invariably reach the upper stethoscope first. In some experiments conducted by the writer, the duration of the inspiration being about two seconds, the interval was approximately one second, varying naturally with the respective location of the stethoscopes and the rapidity of the inspiration. It will be further noted that when the lower stethoscope catches the sounds the upper instrument no longer perceives them. Accidental sounds, a click or two, may be heard, but the shower of crackles has passed. Cause the subject to lie upon a table and observe the relation of the marginal sounds to Litten's phenomenon. It will be found that the marginal sounds are heard as the shadow passes, or just after it passes, the stethoscope. Another experiment is of interest as bearing upon the subject of the respiratory distention of the lung. Mark the inspiratory level as above, and cause the subject to take 10 deep breaths, inhaling as deeply and exhaling as little as possible. As Cabot states, the inspiratory level will have descended nearly an inch. Mark this level and reverse the process, directing the subject to breathe 10 times, inhaling as little and exhaling as strongly as possible. Determine again the inspiratory level and it will be found that it has returned approximately to its first position. If it is found that after repeated deep inspirations the subject is no longer able to produce the marginal sounds as well as at the beginning advantage may be taken of the foregoing observation by causing him to make several forcible expirations, after which it will be found that he can again inspire deeply, and the marginal sounds will be heard as clearly as at the outset, unless he be too greatly fatigued. The marginal sounds are rightly named, being generated absolutely at the margin of the lung. Their cause is believed to be the peeling off of the diaphragm from the chest wall as the lung descends into the complemental space. The costal and diaphragmatic pleura are of course slightly lubricated surfaces and no reason is apparent why their separation should not produce more or less moist sounds if such separation is effected with vigor. In fact, under the circumstances, no other explanation is possible unless it be friction of the tip of the lung as it plows its way downward, so to speak, between the pleural folds of the complementary space, which seems the less probable hypothesis.

While we have found marginal sounds present most conspicuously in the lungs of robust men, other writers, observing the presence of these sounds in early tuberculosis, have drawn the conclusion that they are dependent upon deficient action of the diaphragm. For example, Von den Velden[1] states

that the marginal sounds are generally not to be demonstrated in coughing consumptives and large infiltrations on account of the ventilation of the margins caused by hard and frequent coughing. He considers that the marginal sounds constitute an auscultatory control of the activity of the diaphragm, which ranks with Litten's phenomenon but in the reverse way. While the presence of Litten's phenomenon shows mobility of the diaphragm, the marginal sounds are an evidence of its inactivity. And De la Camp[14], with Von den Velden's approval, expresses the opinion that marginal sounds are to be considered as the auscultatory equivalent of Williams' phenomenon. Now Williams' phenomenon, if present in tuberculosis of the upper lobe, is an evidence that the disease is sufficiently extensive to produce an inelasticity of the lung which prevents the diaphragm from readily descending to its normal extent. The lower lobe is, however, still capable of distention under forced inspiration, and hence the marginal sounds may be produced, whereas in "the coughing consumptive" the lower lobe is habitually more or less distended and as a result of this the diaphragm is incapable of excursions of sufficient amplitude and force to produce the marginal sounds. The theory set forth in this paper differs from that of the writers cited in that it assumes that the marginal sounds are a normal phenomenon which occurs as long as the lung has its normal volume, and ceases when the lung has become overdistended, while the other theory assumes that the marginal sounds only occur during the process of expanding an atelectasis.

Dr. W. B. Borden, examining 75 ambulant tuberculous patients, under the writer's direction, for Litten's phenomenon with a view to determining whether there is any relation between this sign and the marginal sounds, found Litten's phenomenon present in 58 out of 75 cases. Of these 58 cases 46 had marginal sounds. Marginal sounds were present in 48 out of the 75 cases. Of these 48 cases, 46 presented also Litten's phenomenon. From this study it is evident that there is a very close connection between Litten's phenomenon and the marginal sounds, in that both are dependent upon freedom of movement of the diaphragm.

3. Sounds originating in the sternum and in its articulations: We distinguish three kinds: First. Fine sounds resembling crepitant râles found over the sternum. Second. Coarser sounds resembling medium moist râles, or sometimes finer moist râles, which originate in the costosternal articulations. Third. Clicks which likewise originate in the costosternal articulations. Sounds of the first class are heard during deep inspiration over the sternum. They resemble crepitant râles, but are not quite so fine and dry. The quality of the sounds is different from pulmonary râles. The adjective "cartilaginous" best describes it. The crepitations are numerous. There is a shower of fine crackles. They are sometimes heard only over the manubrium, sometimes only in the vicinity of the ensiform appendix, but usually are found best over the gladiolus. They are sometimes heard over a limited area on ordinary breathing, while inspiration following expiration and cough develops them over the entire sternum. These sounds may be elicited over the sternum, near the insertion of the great pectoral muscle when the arm is swung forcibly from before backward, the breath being held. These sounds are not transmitted beyond the sternum. They are believed to be due to the bending of the bone or of the costal cartilages by the respiratory act, or by the tugging of the attached muscles. Sounds of the second class are heard loudest over the costosternal articulations during deep inspiration. They imitate medium sized moist râles. They are transmitted to the neighboring soft parts and sometimes for several inches along the rib to which the articulation belongs. They do not appear to be propagated to the other side of the chest. They are distinguished from pulmonary râles by the fact that they are heard loudest over the articulation and may be transmitted along the rib with diminishing intensity. In some cases the diagnosis is difficult. These sounds may sometimes be brought out by swinging the arms while the breath is held. The sounds are heard oftenest, in the writer's experience, over the 2d costal articulation of the left side. They are usually confined to one articulation but in one case they were heard over the 2d, 3d, and 4th articulations of the left side at the same examination, and were progagated along the 2d rib to the mammillary line and nearly to this line along the 3d rib, the subject being a young athletic man in good health. The clicks of the third class are sounds resembling articular sounds. They are single sounds, rather coarse, of a "bony" quality, not usually loud, and are propagated along the rib to which the articulation which generates them belongs, and may be occasionally transmitted through the sternum to the other side of the chest. In one case the sound which was produced in the 4th costal articulation of the left side was propagated along the corresponding rib as far as the anterior axillary fold. This finding was twice corroborated by other observers. The sound is rare and has only been discovered in men of athletic training. Of 19 healthy young men examined especially for sternal sounds, the sounds were found in ten; in one of these clicks of the 4th costosternal articulation were heard; in another, sounds like moist râles over the articulation of the 2d rib, left side, extending 1½ inches along the rib; the remaining eight had the finer sternal sounds. Special attention is invited to the case first mentioned for the reason that this man understood well the method of expiration and cough, and coughed with great vigor during the examination. It is believed that if this method were thoroughly understood by the men the percentage of positive results would have been much increased. Some of the men did not grasp the idea at all; others carried it out quite imperfectly. The examination is fatiguing and the usual preponderance of inspiration over expiration diminishes the time of effective breathing so that thorough examination of a subject is difficult. The finer sternal sounds are fairly constant, but there is an irregularity in the appearance of the coarser sounds which is not to be explained altogether by the above considerations. If it is correct to suppose that the coarser râles and clicks are produced within the articulations an explanation of their intermittent appearance may be sought in the laws which govern the production of sound within joint capsules. As is well known, the snapping sounds produced within a relaxed joint capsule depend upon a relaxation, or at least a certain optimum tension, of the muscles which control the joint. For this reason the sounds are best heard when the joint is first put in motion after a period of rest, disappear after brief use, and often cannot be again obtained until after rest. In some cases the tension of the muscles must be exactly at the optimum degree or the sounds will not be produced at all. This is illustrated by a condition to

which the writer is subject. If he bends the trunk forward, a position is sometimes reached, more or less by accident, in which a snapping sound is produced during expiration, near the ensiform cartilage. The phenomenon subjectively is rather a motion than a sound, but the noise of the slip is perceptible to others at a distance of a yard. The accompanying sensations lead to the diagnosis of motion at the articulation of the 7th costal cartilage on the right side with the sternum. Now, though the sound may sometimes be reproduced indefinitely, as soon as others attempt auscultation it immediately disappears. A certain degree of muscular tension appears to be necessary to produce the phenomenon, and even the idea of an examination suffices to change the tension so that the sound disappears.

It appears probable that the clicks are made possible by a stretching of the joint capsules in the athlete which permits a greater separation of the articular surfaces than is found in the subject whose thorax has not been subjected to severe strain. All three classes of sternal sounds may be found simultaneously in the same subject. Sounds resembling the moist râles of the second class of sternal sounds may be obtained on auscultation of a freshly removed sternum while an assistant holds the bone firmly with one hand and moves the costal cartilages with the other.

From the difficulty which exists in distinguishing the sounds originating in the articulations from the râles of morbid processes in the underlying lung, observations made upon well-marked cases of tuberculosis would naturally be viewed with suspicion. For that reason the writer has cited solely the results obtained in the examination of healthy men. It is desired now to mention briefly, cases of suspected and real tuberculosis in which the sternal sounds caused difficulties in the diagnosis.

Case I.—A patient who had had a winter cough was examined by his physician and the diagnosis of pulmonary tuberculosis was made. He then consulted a specialist who, having given 5 mgm. old tuberculin without reaction, declared that tuberculosis was not present. Nevertheless the patient went to the Southwest and was seen by a physician, a very good diagnostician, who, after examining the patient's lungs, said that he would stake his professional reputation upon the presence of pulmonary tuberculosis notwithstanding the fact that the tuberculin test had been negative. The patient then came under the writer's care. He was a middle-aged man of very good physique, well nourished, and appearing in good health. There was no fever further than occasional rises of a few tenths of a degree under rest and full feeding, no cough, no expectoration. The lungs presented nothing abnormal except that over small areas in the second and third interspaces on the right side close to the sternum, and in the second interspace on the left side also close to the sternum, what seemed medium sized moist râles were heard very distinctly on deep breathing. These were considered at first to denote small tuberculous lesions. But the progress of the case led to suspicions as to the diagnosis. The situation of the supposed tuberculosis was unusual for initial lesions. The continued good health as time went on, the entire absence of cough and expectoration, the history as regards tuberculin, all seemed incompatible with the supposed significance of the physical signs. The patient was reexamined with special reference to sternal sounds. The sounds in the second and third interspaces could be elicited when the patient held his breath and swung his arms. He had also the finer sternal sounds very well marked. He was discharged from treatment, returned to work, and has been in fine physical condition, as he states in a recent letter, for more than a year.

Case II.—A young cavalry lieutenant, aged 25, whose father died of tuberculosis, had two attacks of pneumonia at West Point six and seven years ago. There was an obscure history of occasional attacks of asthma in 1907. After great exertions in a desert country he fell sick and was admitted to hospital in California for a cold and diarrhea. Here he had a slight attack of asthma, reacted positively to the v. Pirquet test, and was sent to Fort Bayard. On examination, February 24, 1911, no morbid signs were discovered except pleural adhesions over the lower lobes, more marked upon the right, resulting, probably, from the pneumonic attacks. As a result the latissimus dorsi muscles were hypertrophied, and the upper thorax was unusually flexible. In spite of the handicap of the pleural adhesions the patient was a sprinter and active and athletic in every way. Marginal sounds were absent. Very marked sternal sounds propagated along the ribs were obtained. After a few weeks of rest the patient was returned to duty, April 4, 1911.

Case III.—An officer, aged 33, admitted February 10, 1911. Health impaired by tropical service in 1907. Has not felt well since. Somewhat neurasthenic. Recent history of positive sputum for tubercle bacilli, which is probably a mistake. Patient has no sputum, no cough, and no fever. An attack of influenza in December, 1910, with high fever. Some impairment of percussion note and prolonged expiration over both apices, especially the right. Sternal sounds heard over ensiform cartilage and manubrium on ordinary breathing. On expiration and cough they are heard over the entire sternum and are propagated along 2d and 3d ribs, right side, very plainly. The sternal sounds at the 3d costal articulation are perceptible to the patient when the breath is held and the right arm swung. The patient has been a baseball pitcher. The right clavicle is very movable. The sounds of motion at the right clavicular articulation are loud, but plainly different from the sternal sounds already mentioned. Diagnosis made was arrested tuberculosis, both apices. Patient was returned to duty in August, 1911.

Case IV.—A professional man, aged 50, devoted to athletics and a hunter of big game, suffering an impairment of health was declared to have tuberculosis. At a later time the diagnosis was withdrawn as based on insufficient evidence. The disease was supposed to be located in the left axilla. Examination by the writer showed the presence of marginal sounds in the left and also in the right axilla. A well-marked click was heard on deep inspiration over the 4th costal articulation, right side, which was propagated with distinctness along the rib for a distance of about three inches. The sternal sounds of the first class were numerous and loud, and, as has been noticed in other athletes, were somewhat coarser than in other subjects.

The writer has not been able to discover any mention of the sternal sounds in the literature accessible to him. As for their practical importance the finer sounds might be mistaken for evidence of disease of the anterior margin of the lung. Their quality, however, should attract attention. The clicks, so far as known, have not led to error of diagnosis. Perhaps sufficient evidence has been presented to

show that the sounds of the second class, which simulate râles, may cause confusion and it is this class of sternal sounds which especially calls for further study. The location of the loudest sounds and the propagation of the sounds along the rib in diminishing loudness should excite suspicion. But if the transmitted sounds meet with a "layer of good conducting infiltration or of thickened pleura," or "of small cavities acting as resonators," such as Turban assumes in explanation of some of his results in the study of the transmission of râles by bone from one lung to the other, it is apparent that an examiner who is not on his guard may be misled as to the nature of the lesion and may even diagnosticate a widespread tuberculous infiltration when none whatever exists. Special care is requisite in examining the lungs of the athlete on account of the variety of sounds producible in his mobile chest. Turban mentions a patient who considered that his medical advisers were proficient in physical diagnosis if they required him to cough during examination of the lungs. The writer agrees with this patient. Cough during examination is essential to determine the extent of a lesion and to bring out râles in seemingly quiescent lesions. The method of expiration ending in a cough and followed by a full inspiration has the advantage of bringing the expiratory muscles into action and of thus tending to diminish or prevent distention of the lungs from repeated inspirations. If efficiently performed it will be found, in the majority of cases, the best method of determining the presence of moisture within the lungs. But it is also the best means of eliciting marginal sounds, and often, at least in the untrained subject, the only means of producing sternal sounds. The use of the method, then, should be guarded by full knowledge of the fact that it may bring forth a variety of sounds not due to morbid processes within the thorax.

4. Another sound which resembles fine râles has not been described, so far as the writer knows. If the stethoscope is pressed rather firmly upon the skin of certain patients over muscular areas of the thorax, a fine crepitation is produced. This crepitation can be caused by a second, sometimes by a third, pressure upon the same spot, rarely by more than three. The crepitation is close to the ear and is like extremely fine, moist râles. It has never been detected except over the pectoral muscles and the latissimus dorsi.

In cases in which the phenomenon is well marked the crepitation is produced by the rise of the muscle against the stethoscope in full inspiration, though the instrument be lightly and properly applied, and under these circumstances a careless examiner may be misled. The sign is rather rare. It seems to be confined to patients of rather thick, not dropsical, subcutaneous tissue. With a little experience it is easy to predict the cases in which at least it will not be found. In one case the sound was elicited only over a plexus of small varicose veins over the left pectoral muscles on a level with the top of the axilla. In other cases the soft parts have appeared normal. It was found by Borden in 6 out of 58 healthy soldiers. Case I, above mentioned, presented the phenomenon to a marked degree. That it may lead to confusion in diagnosis is shown by the following case:

Case V.—A young man of 19 had a winter cough and was somewhat overworked. Being examined physically for appointment as non-commissioned officer of the militia in an Eastern State he was rejected on account of pulmonary tuberculosis. He was examined at a later time by a specialist who confirmed the diagnosis. He then came to New Mexico and was examined by the writer in 1910. The site of the supposed tuberculosis was the left axilla. There were marginal sounds at the base of the lung at this point and fine crepitations were exquisitely manifest in the latissimus dorsi. No morbid signs were present and the patient was assured that he had no tuberculosis. Not altogether trusting this diagnosis, with a view to remaining longer in a favorable climate, the young man obtained a position with a bridge gang which was constructing a high steel bridge. Although unfamiliar with the work, he was able to endure its severity with physical advantage, and after laboring for several months he returned to the East, having gained an inch in height, two inches in chest expansion, and fifteen pounds in weight, quite convinced that he had no tuberculosis.

Sahli[9] mentions, besides the active muscular sounds of the thorax, a so-called passive variety which he says "may be produced by the displacement of bundles of muscular fibers under the stethoscope by light movement of the instrument or by the respiratory excursion of the chest itself. These sounds may be recognized by intentionally moving the stethoscope and so reproducing them when the patient is not breathing. Other sounds originate from similar conditions, as, for instance, that produced by pressing the stethoscope over the lobulated fat of the female breast. These sounds frequently resemble crepitation very closely." Sounds caused by the slipping of muscular fibers are, in the writer's experience, most marked over the pectoralis major in the anterior axillary fold. They may be reproduced by movements of the stethoscope as Sahli says, but by gentle lateral movements, not by repeated intermittent pressure as in the phenomenon now under discussion. These latter sounds are evidently not due to active muscular contraction, first, because they are quite different from the well recognized muscular sounds especially common over the trapezius; secondly, because they are heard best when the underlying muscle is passive; thirdly, because they are not heard at all over spare, well-muscled chests in which purely muscular sounds should be heard most readily. They are finer sounds than those produced by pressure of the stethoscope upon lobulated fat. They are distinctly a phenomenon of juicy tissue, whether subcutaneous or muscular is uncertain. The question suggests itself whether they may not be a sign of retention of water. They do not occur in clinical edema in which the tissues are filled with fluid. But if the state of the nutrition be such that there is a tendency to an accumulation of fluid above the normal, but short of true edema, the fluid might conceivably be displaced by pressure with the production of sound. If this be the explanation no reason is apparent why the phenomenon should be confined to the thorax.

FORT BAYARD, N. M.

THE TREATMENT OF ACUTE LOBAR PNEUMONIA.*

BY CHARLES EDWARD NAMMACK, M.D., LL.D.,

NEW YORK,

VISITING PHYSICIAN TO BELLEVUE AND TO ST. VINCENT'S HOSPITALS, PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE AT NEW YORK.

FROM time to time an article will appear in current medical literature advocating some special line of treatment for pneumonia, and claiming a remarkably low death rate for the cases so treated. Such articles are usually based on a limited number of cases, occurring in the same locality and in the practice of one individual, whose temporary success in a series of cases awakens his enthusiasm. But when such statistics are compared with those of a vast number of cases collected from the general hospital and private practice throughout the United States, as was done by Wells in 1904,[1] it will be seen that pneumonia still continues to exact its toll of 20 to 25 per cent. of deaths. Thus, of 465,400 cases, Wells found a mortality of 20.4 per cent., and among 43,455 cases collected by Norris and Musser 21.06 per cent. died.[2] These figures form a striking contrast to the reports of some observers, who claim a percentage recovery of from 95 to 100 per cent. in a limited number of cases treated according to some pet plan.

It is of course understood that pneumonia is an acute generalized infectious septicemia, with a localized expression in the lung; yet many practitioners seem to be unable to rid themselves of the obsession that the lung must furnish the sole object of investigation and attack. We read of measures addressed to the local condition as if this alone were the enemy to be overcome; yet the lung presents exactly the same condition after the crisis, when the danger is over, as it did a few hours before, when the patient's life trembled in the balance. Patients may be overwhelmed by the general toxemia when the physical signs show little or no lung involvement, or may exhibit extensive lung involvement with little or no general disturbance.

The patient with the pneumonia, and not the pneumonia that is with this particular patient, must furnish then our fundamental concept of the management of the individual case. The obvious corollary is that there can be no specific adapted to every case, but that, inasmuch as the disease is self-limited and terminates by crisis, our efforts must be directed to facilitating the crisis, supporting the patient, preserving him from unnecessary stress and strain, and meeting emergencies as they may arise. Clinically, we meet with three classes of cases: (1) those who will recover in spite of all you may do to them; (2) those who will die in spite of all you can do for them; (3) a very large intermediate class in which the result may depend upon skillful, judicious therapeutic intervention. During an epidemic of pneumonia, or during the prevalence of influenza, which is so often complicated by pneumonia, certain measures of prophylaxis are advisable for the individual, for the community, and for the physician himself. Individual prophylaxis is best secured by keeping the nose, mouth, and throat as clean as possible by antiseptic sprays, mouth washes, and gargles; by the avoidance of crowds of coughing and sneezing persons; by abstaining from the use of alcohol, which paralyzes the sentient sentinel nerves of the respiratory mucous membrane, and by guarding against exposure, exhaustion, and privation.

Communal protection demands that the infected person should be isolated and his discharges carefully disinfected. The physician who takes charge of a case of pneumonia assumes a grave personal risk, and should have thorough knowledge of the disease, sufficient physical endurance, freedom from alcoholic or drug habits, unclouded judgment, executive ability, and self-confidence.[3] Even then pneumonia cannot be prevented, but it need not be invited. A number of our modest brethren allow their patients to believe that a "threatened pneumonia" can be aborted, but it is hardly necessary to say to this audience that any abortive treatment of acute lobar pneumonia is theoretically impossible.

Given a case of pneumonia then, in private practice, the first question that naturally arises is, have we a specific for this generalized septicemia? If all pneumonias were caused by the pneumococcus, and if all pneumococci were alike, we might hope for an affirmative answer. At present the answer is—no. Our dependence then must be on the general measures to meet the indications previously outlined, and I have nothing new to offer you on that heading, but only a recital of the means that have helped me in hospital and private practice during thirty years. As soon after the initial chill as possible, the patient is put into a warm bed and given a mustard foot bath in the bed, under extra covering and with vigorous rubbing of the legs for thirty minutes. He is then given an enema of two ounces of epsom salts with two ounces of glycerin and twelve ounces of water. I avoid the use of the customary hypodermic of morphine at this stage unless pain is so great as to be uncontrollable by strapping the chest and by hot applications, or unless nervous excitement is so great as to seriously disturb circulatory equilibrium. My next order is for either ten grains of blue mass or a powder of calomel, five grains, with sodium bicarbonate, fifteen grains, to be followed in six hours by a saline laxative. Thereafter and during the progress of the disease I order a high, hot, large normal salt solution irrigation every morning, and also the epsom salts and glycerin enema every evening, because I believe in stimulating the splanchnic circulation, keeping the lower bowel empty, and preventing the development of troublesome tympanites later in the disease. For the same reasons I avoid overfeeding the patients, avoid articles of diet which may produce flatulence, and forbid the use of beverages containing carbonic acid gas. Patients are fed, however, every three hours with milk, eggs, broths, coffee, and other fluid foods, with water enough to make up an aggregate of five pints in twenty-four hours. They are not awakened from sleep at night. Sleep should not only be encouraged, but secured if need be by one of the newer hypnotics, or by morphine if you must, before it passes into marked insomnia with exaltation or delirium. A delirious patient requires constant vigilance. The sick room should be well lighted, and solicitous ignorance on the part of rela-

*Read before The Bronx Medical Society, December 13, 1911.

tions should not stand in the way of the unlimited admission of free, fresh, flowing air. It seems to me, however, that we have been carried away by the glowing accounts of success in pneumonia by putting patients out on balconies and roofs. Pure air at a temperature of 65 F. has always satisfied me, with the exclusion of visitors and of the consideration of any business matters. The nurse should be efficient but not meddlesome. Too much meddlesome medication does more harm than good. Drugs and food should be given together if possible, and the patient's toilet wants should be attended to at three-hour intervals, and he should have absolute quietude of mind and body between these intervals.

Next I endeavor to have an accurate blood count made, including a differential enumeration of the leucocytes, and to have a thorough uranalysis done. A daily blood chart thereafter, with a daily examination of a twenty-four hours' specimen of urine, will keep us alert for complications. A comparison of the blood pressure with the pulse rate will also give us valuable prognostic and therapeutic indications. If the pulse rate is less than the blood-pressure reading the patient is doing very well. Some clinicians believe that the remarkable reduction of arterial pressure which accompanies the onset of the disease should be encouraged, and such practitioners administer remedies to favor this circulatory depression, such as veratrum viride, aconite, nitroglycerin, iodide of potassium, etc. Others presume that Nature is mistaken, and endeavor to correct her error with digitalis, adrenalin, etc. I am one of those who believe that low blood pressure can only result in vasomotor paralysis with consequent stagnation of the bloodstrain, so that the tissue cells lose their accustomed stimulus and are consequently constantly bathed in a solution of their own wastes.[3] Therefore I use from the outset strychnine, caffeine, alcohol, and camphor. I have not had the same success with ergot that has been claimed by some of my colleagues. Nor do I place much reliance upon digitalis in the presence of high fever. After the crisis, however, digitalis may be clearly indicated. Adrenalin is a drug which, when given hypodermatically in good-sized doses, helps in tiding over the crisis.

The fever in pneumonia causes the relatives, and sometimes the attending physician, a great deal of unnecessary anxiety. Fever is a specific reaction against injurious materials which affect the tissues, and is, in its essentials, a protective reaction.[4] Accepting this definition, fever requires no interference unless it becomes high enough to add to the poisoning of the vital centers. A temperature of 104° F., associated with a moderate leucocyte count, with a blood pressure which is higher in the manometer reading than the pulse rate, and with clear heart sounds, gives a better outlook than does a temperature of 102° F., with a low leucocyte reaction, with low systolic arterial pressure, and a muffled first sound with a pulse of 120. Hyperpyrexia, however, indicates danger, and should be promptly met by the application of cold compresses, cold sponging, and ice bags to the chest. Coal tar antipyretics should never be used. Quinine still has some ardent advocates, and its hypodermatic use has lately been extolled for its chemical and antitoxic, rather than its antipyretic, effect.[5] But, inasmuch as it is the death of the pneumococci, and not the neutralization of their toxins, which must precede the recovery of the patient, this action of quinine would seem to be inadequate. Personally, I believe that alcohol is a good antipyretic. Alcohol reduces temperature by increasing heat loss by evaporation and radiation; it lessens heat production; and, most valuable of all, it supplies an easily oxidizable fuel to be burned up instead of the tissues. In patients accustomed to its use, especially in the alcoholic pneumonias so numerous in Bellevue Hospital, I use it with a free hand, in half-ounce doses frequently repeated, unless coexisting kidney complications contraindicate. Its drawback is that it promotes vascular relaxation, but this risk must be accepted when the alcohol is needed.

The pleuritic pain of the early stage of pneumonia is usually severe, sometimes agonizing. If possible, I avoid the use of morphine, which obscures the symptomatic field, dulls the nervous reflexes, and causes an insistent demand for its repetition by the patient, which is dangerous to accede to. Strapping the chest, local applications, the Paquelin cautery, and mental encouragement should be used to the limit, before morphine. Cough may also be distressing in the early stages, but here again the use of any opium preparation is a two-edged sword.

After the stage of onset, the toxemia of pneumonia becomes manifest in the functions of the cerebrum, of the cardiovascular and of the respiratory systems. The first brain symptoms are excitation, restlessness, insomnia, and delirium, followed in severe cases by depression, stupor, and coma. The measures already described, of aerotherapy, hydrotherapy, and elimination by the bowels, skin, and kidneys, have done something to forestall these dangers, but if pronounced they may require enteroclyses of physiological salt solution, or the Murphy drop method, with increase of diaphoresis by hot packs, and an ice helmet to control delirium. Insomnia may require trional in hot milk, chloralamid in cold whiskey, or, if unavoidable, ¼ grain morphine hypodermatically. The cardiovascular symptoms are harder to conquer, and, when pronounced, compel us to use our remedies by intramuscular, rather than hypodermic, injection, since Meltzer has shown that muscular tissue contains such a network of veins that injections therein are almost as promptly taken up as when given intravenously. My own faith rests firmly on strychnine and alcohol for steady and continuous effects, despite the doubting Thomases of the pharmacological laboratories. I hold camphor in sterilized oil and adrenalin in reserve for emergencies, and believe that I have seen good results in Bellevue from the intravenous injection of 1 milligram of strophanthin in cardiac collapse, after the failure of the first mentioned remedies.

The dyspnea of mechanical obstruction by involvement of large portions of lung is best relieved by oxygen. Not the canned oxygen supplied by manufacturers, but that of the free, fresh, flowing air. Edema of the lungs, if dependent upon low arterial pressure, will be helped by intramuscular injection of adrenalin, which raises the blood pressure by stimulating the vasoconstrictor fibers of the splanchnic vessels and thus drives the blood into the brain, lungs, and heart. If associated with high blood pressure, artificial respiration seems to facilitate the discharge of serum from the tubes and to facilitate the pulmonary circulation.[6]

When your patient has safely come through all these dangers, and has entered upon convalescence, keep him in bed a week longer, carefully estimating each day the working power of his heart, and keep

him a second week in a chair on a sunny porch. The complications of pneumonia are many and cannot be touched upon within the time limits of this paper. One word only. Cases of "unresolved pneumonia" will resolve themselves into post-pneumonic empyema upon the sterile introduction of an aspirating needle.

If I may be allowed to summarize this discursive recital of an old story, I may say that the factors upon which I hope for success in the treatment of pneumonia are isolation, ventilation, disinfection, elimination, and support. The factors making for fatality are, half enough air, half enough water, half enough rest, too much meddlesome medication. Our search for a specific has hitherto been fruitless. Serum therapy, from which so much was hoped, has thus far signally failed. There are several reasons for this failure which, however, need not be gone over here.

In our line of treatment we must consider two things: the action of the infecting organism on the tissues; the defensive powers of the host. With the former we can do very little by therapeutic means. The latter must be fortified by every means at our command. Death ensues from an overwhelming extent of the inflammation, or from toxemia, producing the condition known as cardiac failure. The entering wedge of this condition is laid at the very beginning of the attack in the vasomotor paresis which transfers a great excess of blood from the arterial to the venous circulation, and this loss of circulatory equilibrium must be fought from the very outset. The time to treat "heart failure" is before it has developed. The physician who withholds cardiac support until his patient presents a dry brown and fissured tongue, low muttering delirium, a pulse rate of over 120 with a low arterial pressure, and a feeble first mitral sound with a failing second pulmonic sound has lost his golden opportunity. In spite of all our measures of support, this condition may develop, and it is here that venesection sometimes gives brilliant results by abstracting a pint of toxin-laden blood, and diluting the remainder by introducing liquids by the mouth or rectum, or by hypodermoclysis. Venesection should never be done in the very young, the very old, the anemic, or the weak. It is not indicated in the stage of onset, as the formation of the exudate at that time consumes from 2 to 4 pints of blood.

The view that heart failure is due to the poverty of calcium in the circulating blood in pneumonia has recently been put forward, and the administration of calcium chloride in 10-grain doses every three hours is eloquently advocated.[7] For the same reason, the free use of sodium chloride has been urged. These remedies have no deleterious effects, and their use may be added to that of the other measures herein recommended.

MULTIPLE HEREDITARY TELANGIECTASIS OF THE TONGUE, TURBINATES, AND SEPTUM WITH RECURRING HEMORRHAGES.*

BY CORNELIUS DOREMUS VAN WAGENEN, M.D.,

NEW YORK.

A SEARCH of the literature of this subject discloses a small group of ten families, which have been assembled, since Babbington[1] first attempted to describe this disease in 1805, by the individual reports of Wickham Legg[2], Chari[3], Rendu[4], C. O. Hawthorne[5], A. Brown Kelly[6], Parkes Weber[7], and William Osler[8]. Doubtless there may have been others, but if so they either have been withheld for private reasons, have been erroneously classed with hemophilia, or have been incorporated in that comparatively numerous group of the acquired angiomata, such as, for example, occur in the course of a cirrhosis of the liver, or are said to be diagnostic of certain forms of intraabdominal malignancy.

This patient came under the writer's observation, at the Vanderbilt Clinic, in the early days of September, 1911, and in the service of Prof. William Kelly Simpson. Mrs. E., aged 32 years, a native of Russian-Poland, but resident in this city for the past seven years. Of the family history nothing more remote than her parents can be definitely learned. Her mother, now 55 years of age and living in Russia, has suffered from frequent attacks of bleeding from the nose since early childhood, but she has not been known to bleed from the tongue or other parts of the mouth, the skin of the head, face, body, or extremities, or from the rectum. Regarding the father's health no information whatever is obtainable. Four brothers and three sisters are living in Russia, and all are healthy, save two brothers, one twenty-seven and one twenty-two years of age, each of whom has suffered from epistaxis since early childhood, but has never had any hemorrhage from any other part of the body. This patient is 5 feet 5 inches in height and weighs 193 pounds. In the ten years of her married life she has had six normal births and one miscarriage. Four of this issue died in the early months of infancy, but in none was any bleeding noted or any "spots" of any kind, such as are present in the mother. The two living children, a boy and a girl, aged respectively 3¼ and 8½ years, are apparently perfectly healthy, and have manifested none of the phenomena of the grandmother, mother, or uncles. This patient has a varicose condition of the right lower extremity which followed the first pregnancy. For the past nine years she has presented pretty much the same appearance as now. During this period she has had bleeding from the tongue and nose, but never from any part of the body. These attacks have been irregular in point of time and have begun without warning or known cause. There has never been any swelling of the lower extremities, other than the varicosity above mentioned, nor any trouble with any of the articulations. There have been no subcutaneous extravasations or persistent contusions. There have been no exsanguinating hemorrhages from relatively slight wounds. She has never had any prolonged illness, especially none attributable to the stomach, liver, or gall-bladder. Some three years ago she underwent

*Read at the meeting of the Section in Laryngology and Rhinology of the New York Academy of Medicine, October, 1911.

an exploratory laparotomy at The Women's Hospital. Dr. Edward W. Pinkham, the operator, has informed me that there was nothing in her condition which contraindicated abdominal incision.

On examination the tongue was found irregularly studded from base to tip with numerous discrete, elevated, pink to cherry-red, and purple spots, especially prominent along the free border, and of the varying diameter of 1 to 3 mm. In addition, a similar pinhead tumor was found on the anterior tip of each inferior tubinate body, and still another on the mucous membrane covering the left side of the cartilaginous portion of the nasal septum. In other respects the upper respiratory tract was entirely free from involvement. Several cherry-red pinhead spots on the face and arms, which had, however, never attracted her attention, completed the findings. Two days later the writer witnessed the first of several nasal hemorrhages which occurred during her presence from time to time in the clinic building. The flow was moderate, but continuous, quickly saturating her handkerchief. The blood seemed to swell up into the left inferior nasal fossa. Careful sponging disclosed the bleeding point to be the septal tumor above located. An application of thrombokinase[6] promptly stopped the bleeding. At this sitting two new spots were noted at the junction of the hard and soft palate and to either side of the median line. She was placed on twenty-grain doses of the lactate of calcium, four times daily and given the tube of thrombokinase with instructions for its use in the presence of bleeding. A four-day quiescent interval followed, considered accidental, as a subsequent period of irregular attendance without any definite treatment served to reestablish the original condition. This period of apparent inaction afforded the writer and his associate, Dr. A. S. Blumgarten, an opportunity to investigate the condition of her blood. The coagulation time seemed to be a matter of considerable importance and several methods were employed, taking not only the patient's blood, but also as a control that of her children, of Dr. Blumgarten, and of the writer. Three methods were employed with the following results:

	Mother.	Boy.	Girl.	Dr. B.	Dr. v.W.	
Needle and slide	3 min.	2.30 min.	2.30 in.	2.40 min.	2.30 min.	
A. E. Wright	3.20 "	2.30 "	2.30 "			Thermos bottle used as constant heat chamber.
Rudolf	2.30 "	2. "	2. "			

In hemophilia the time is 6, 9, to 14 min., or incomplete in an hour's time. Dr. Blumgarten also made a microscopic examination: Red blood cells, 3,600,000; white, 12,000; hemoglobin, 80 per cent. Differential count: polymorphonuclears, 60 per cent.; large lymphocytes, 9 per cent.; small lymphocytes, 30 per cent.; eosinophiles, 1 per cent.; basophiles, 0 per cent.; blood plates, somewhat increased.

Dr. Howard Fox, in reporting the Wassermann reaction as negative, stated that there was no unusual behavior at the site of his withdrawal of blood. Dr. Ward A. Holden reported a normal condition of the eyegrounds and vision. Her menstruations have been regular, with a duration of three to four days and a moderate flow. Retroversion of the uterus is present.

Dr. A. McI. Strong of the Department of General Medicine determined the average systolic pressure to be 130 taken on a Janeway sphygmomanometer, and added, after a careful physical examination, that he considered her "a very normal person."

With the above data in hand it is the writer's belief that the phenomena of this patient's life, as well as that of her relatives, place her and them in the family group which gives title to this paper. Any attempt to connect her case with the acquired type may be at once dismissed, but some confusion of thought may arise in a differentiation from hemophilia. In such a contingency the tumors and dependent hemorrhages seem the only points of possible agreement. Although a search of the literature has been made, no case of hemophilia has been found which presents such evidence of persistent vascular excess as here obtains. The hemorrhage may occur, but is not so prolonged or so exsanguinating. In all other respects there seems to be a marked absence of the salient features of a purely bleeder family. Viewed from the standpoint of heredity, we must at once apply the generally accepted belief that in hemophilia the female is exempt, though capable of transmitting it, while the male only gives evidence of the disease. Dr. Francis P. Kinnicutt, writing in the June number of the MEDICAL RECORD, 1905, lays down certain laws governing hemophilia transmission. (1) As a rule the daughters of a bleeder father are exempt from the evidence of the disease, but transmit it to their offspring. (2) The sons of a bleeder father are also, as a rule, exempt and do *not* transmit it to their offspring. (3) The daughters of a bleeder father may transmit the disease to a single one, to several, or all of their offspring. (4) Where there are several daughters the capability of transmission to offspring may be confined to a single one, or all the daughters may transmit it. (5) Occasionally there is a direct transmission from father to son throughout several generations. (6) The disease does not appear in the issue of the sons of a bleeder family who are not themselves bleeders.

Now, in the family group of which it is claimed this patient and her relatives are added examples as many *females* as males have been afflicted. In this patient's family even the peasant obtuseness to family traits and characteristics gives a very definite equality between the sexes, and it is quite possible that an examination of her ancestry at first hand would yield other instances.

The span of life in hemophilia is short, while in these cases it is quite variable, one patient having been first observed in the sixty-fifth year of life. A. Brown Kelly, however, writes that forty-two seems the most frequent age for dissolution, and October the month of greatest frequency in bleeding.

It must be evident to you that all treatment is beset with unusual difficulties. Indeed, the literature is so engrossed with the diagnostic side as to afford little aid and but cold comfort to patient or physician. For the control of the actual bleeding we seem to have an efficient sterile hemostat in thrombokinase, and one which should be of considerable aid and comfort in the hands of an intelligent and thoughtful patient. The sum total of the therapeusis seems to be the remittent administration of the calcium salts, the chloride or lactate, over long periods. This may be correct in hemophilia, with its lowered or incomplete coagulation time, but in this instance any attempt to hasten an already fairly normal coagulation time would seem to be expending effort outside the blood-vessels. We have here to deal not with any chemical change, but with a permanently dilated endorgan, with weakened walls, and covered by a rarefied mucous membrane. Either or both are liable to break and

bleed under some sudden increase in the blood pressure, such as would follow the common acts of stooping, sneezing, or the movements of the tongue against the teeth in mastication. Obliteration of the lumen of the affected blood-vessel, by destruction of its intima, would seem a reasonable method of attack. With this end in view cauterization, alone or preceded by excision, has been tried by one observer. The result was fairly lasting, but the process was very painful, and was immediately followed by a prolonged and serious hemorrhage. In the facial and other cutaneous lesions the electric needle has met with some success. This method might be very beneficial to this patient if applied to the nasal tumors. For the tongue, the writer has been considering the injection of hot water into the base of these tumors. In other situations this method has been beneficial and is said to cause little or no pain.

THE MANAGEMENT OF INGUINAL HERNIA IN CHILDHOOD.

By WILLIAM FRANCIS CAMPBELL, M.D.

BROOKLYN, N. Y.

It is a surprising fact, gleaned from the writer's personal observations, that there is a marked difference of opinion among practitioners regarding the management of the reducible inguinal hernias of childhood. Furthermore, when a case is presented for treatment and a clear, concise statement is due the parents regarding the advantages of a truss, the management of the truss, how long it should be worn, the proper time for radical operation, the advantages of radical cure, etc., opinion is not only divided among practitioners, it is often confused, misleading, and inept.

Confusion of thought and wide differences of opinion are excusable in the presence of obscure pathological lesions; but the pathology and treatment of inguinal hernia has long since reached a plane of scientific accuracy; and if the fundamental principles are well understood the family physician will anticipate the surgeon in voicing a definite line of procedure which will bring into fine cooperation both physician and surgeon, and the one will supplement, not supersede, the work of the other. For in the hernias of childhood there is special opportunity for team work which will reflect creditably upon both. It must be remembered that in these hernias there is a preoperative period in which intelligent supervision and vigilant attention may be rewarded by spontaneous cure, or failing in this it will carry the child safely over the first few years till a proper time can be selected for operation.

The fundamental principles in the treatment of these hernias are reduction and retention; more specifically, after all causes of intraabdominal pressure, such as tight belly bands, indigestion, constipation, phimosis, stone in the bladder, etc., which cause crying and straining, have been removed; keep the hernia continuously reduced by closing the hernial opening.

This can be accomplished in two ways: (a) By mechanical appliances—truss. (b) By radical cure—operation.

Remember that in infants it is possible to obtain a spontaneous cure by maintaing continuous reduction by means of a truss, but after the second year the chances of cure by this method are doubtful. At this time, however, surgical treatment is eminently satisfactory and restores normal conditions at once. The rule then should be fairly uniform: (a) In infants apply truss continuously as soon as the hernia is diagnosed. (b) After the second year consider radical operation if the nutritional index is favorable.

Treatment by Truss.—Treatment by truss in an infant should begin as soon as the hernia is diagnosed. But this treatment can be efficient only when the principles of the treatment are understood and its application is in the hands of a vigilant and careful nurse. There is probably no surgical appliance which has been more abused, which demands more intelligent supervision and receives less then the truss. The measuring, ordering, fitting and hygiene of the truss are worthy a high order of intelligence—at least the physician should not abdicate in favor of the trussmaker. It is this shunting of responsibility that mars the results.

One of the most important things in connection with efficient truss treatment is the appreciation of the fundamental principle, a truss to be efficient must be worn continuously. That rule is to be interpreted in its literal sense; for it is obvious that the purpose of the truss is to keep the hernia reduced, to prevent its escape into the sac, and to bring about obliteration of the sac. Hence the support must be continuous, day and night, during the bath, when the truss is changed. In other words, from the time the truss is applied there must not be a moment when the hernial opening is left without support. Should the child cry or cough or strain during a moment when the opening is unsupported, the hernia may again protrude and spoil the results obtained by months of treatment.

How can such continuous supervision best be attained?

First: The management of the truss in infants should be under the supervision of the physician, not the trussmaker. The physician should measure, select, fit, and make the first application of the truss.

Second: The nurse should receive specific instructions in reference to the purpose of the truss, the location of the hernial opening, the proper placing of the pad, the hygiene of the truss and the inguinal region, the proper support of the hernial opening by the fingers of the nurse when the truss is removed for cleansing the parts. This instruction is as important as the ordering of the truss, for without it the truss will accomplish nothing but irritation to the infant.

Furthermore, it should be understood that when the physician prescribes a truss he does not dismiss the patient, he accepts a patient, who is to receive his professional care so long as the truss is worn. It cannot be made too emphatic that the cure of a hernia never results from the mere application of a truss; it is truss plus proper supervision. Again, the mechanical treatment of hernia

does not imply that the treatment is to be left to a mechanic. It is more than the mere prescribing of the truss. It implies accurate measurement for the size of the truss; definite instructions as to the type of truss, careful shaping of the truss so that the truss conforms to the patient, not the patient to the truss.

Eliminate once for all the consideration of such unreliable relics as "hanks of worsted" and "folded skeins of Berlin wool," their inefficiency is only equalled by their uncleanliness.

In selecting a truss be sure that it is first, efficient, and second, cleanly. To be efficient it must possess a metallic spring which can be so adjusted to the child that it conforms to the shape of the pelvis and maintains a pressure that holds the hernia without irritating the skin. To be cleanly it must be simple in design, waterproof throughout, so that it may be unaffected by urine, and frequently cleansed.

One of the most important considerations is the hygiene of the truss. Since continuous pressure is the price of cure, it is evident that the skin will tolerate this treatment only with the most scrupulous cleanliness and persistent vigilance. The problem is to prevent excoriations of the skin which is constantly subjected to pressure and soiled with urine.

To this end the skin and truss must be kept clean and dry. The best results are obtained by having two trusses. The truss is kept on while the child is being bathed; when it is removed for cleansing the underlying skin the nurse is instructed to maintain pressure with the fingers over the hernial opening. The skin is then cleansed and sponged with alcohol and witch hazel, dusted with talcum powder, and the clean and dry truss adjusted in place. This is to be repeated as often as necessary to keep the skin clean and dry. Should excoriations of the skin occur, apply zinc oxide ointment.

After the truss is prescribed, fitted and shaped, and full directions given for the after-care, the physician's supervision is still essential, for the child that wears a truss is a patient until the hernia is cured. One important fact must be kept in mind —the child is growing, and the truss must be changed and adjusted to meet the demands of growth. Hence the patient should be seen at regular intervals; for the mechanical treatment of hernia, especially in children, will be successful only in proportion to the careful supervision of the family physician.

After the age of two years, if the hernia still persists, the truss should be abandoned and a radical cure performed because: 1. The chances of cure steadily diminish up to the age of puberty. 2. Truss pressure causes atrophy of the underlying muscles, thereby diminishing the protection afforded by the muscles, and lessening the chances of radical cure. 3. The wearing of a truss interferes with proper exercise and thus interferes with bodily development. The child who wears a truss is handicapped in the struggle for existence. 4. The cures by truss are often apparent, not permanent. There are many recurrences. 5. Radical operation removes at once the serious handicap with all its disagreeable sequelæ by establishing normal conditions. 6. With the age limitation mentioned above it is the author's experience that the younger the child the more satisfactory the results of operation.

394 Clinton Avenue.

THE IMPORTANCE OF THE ROENTGEN RAY IN THE DIAGNOSIS OF BONE DISEASE.*

By SAMUEL B. CHILDS, M.D.,

DENVER, COLO.

When we consider that the bones are the framework upon and around which the superstructure of the body is built and that for the pursuit of daily vocations it is necessary that this framework be kept intact, or if diseased that that condition be detected as early as possible, it becomes imperative that every means at our disposal be employed in diagnosing these insidious lesions, which many times are so surrounded with the soft structures of the body that palpation is unsatisfactory and subjective symptoms must be largely depended upon for a diagnosis. Furthermore the subjective symptoms of many of the diseases of bone are similar, and, not infrequently, are referred to a part of the bone not affected, yet the methods employed for the cure of these diseases may be very different, palliative in one case, mechanical in another, a conservative operation in a third, while, in still another a radical operation, such as amputation of an entire lower extremity, may be necessary to afford the patient his only chance for recovery.

The field of bone disease is extensive and forms an important part of the work in every general hospital, not to mention the number of cases that are treated daily by specialists at their offices. We have all seen cases of bone disease in which the correct diagnosis has not been made for a considerable length of time, during which period the destructive process in the bone has not been retarded but increased by incorrect treatment.

As the title of this paper indicates, I regard it of the utmost importance that an *x*-ray examination be made early in every case of suspected bone disease, not that necessarily we may be able to make a positive diagnosis in every case from the plate alone, but the evidence from the plate taken in connection with the clinical signs will enable us in many cases to make a correct diagnosis, or at least to have a permanent record of the condition of the bone which may be of great service in watching at a subsequent examination any point that may suggest the possibility of disease. In another class of cases, the *x*-ray plate alone can tell the amount of destruction that has taken place in the bone texture.

No attempt will be made to go into detail in the enumeration of the symptoms in the different varieties of bone disease, but in the following, periostitis, ostitis, osteomyelitis, osteoarthritis exostoses, cysts, malignant disease and tuberculosis, an *x*-ray examination has proved itself of great value in diagnosis and a few cases illustrating some of these conditions will be cited.

Case I.—Man, aged 35, had an operation performed for osteomyelitis of the lower end of the left tibia when fifteen years of age; after several weeks the bone healed and had occasioned no further trouble until twenty years later, March, 1911, when the patient complained of pain in the same locality, associated with some fever. The lower part of the leg was tender on pressure and slightly swollen. At this time, the patient was referred by Dr. Chas. Jaeger for an *x*-ray examina-

*Read at the annual meeting of the Colorado State Medical Society, 1911.

tion. The plate revealed a circumscribed medullary abscess of about three-fourths of an inch in diameter through the external face of the tibia three inches above the ankle joint. At the time of operation, after chiseling through the cortex, the abscess cavity was readily found and the pus evacuated. For several days the patient's condition was satisfactory, and then a gradual rise in temperature to 104° associated with much pain about the left ankle and foot, restlessness, sweats, and great prostration evidenced the fact that the patient was in a desperate condition from sepsis from some focus not yet evident. An amputation of the leg seemed imperative to save the patient's life, for, from the pain in the foot and ankle joint associated with the constitutional symptoms present, the natural inference was that these parts had become infected. At this time an *x*-ray examination was made of the ankle joint and foot and the bones were found to be normal; a slight change, however, was noticed in the texture of the cancellous tissue about an inch below the location of the abscess cavity previously drained. Another opening was made in the bone at this point, no abscess cavity was present, but there was a slight discharge of sero-pus from the cancellous tissue. A communication was established with the opening in the bone previously made, and within twenty-four hours the temperature dropped to 100° with corresponding improvement in all the symptoms and from this time the patient went on to satisfactory recovery. Without the aid of the *x*-ray examinations in this case, an amputation of the leg undoubtedly would have been made. This case also illustrates the fact that in a case of osteomyelitis a focus of infection may remain quiescent for many years only to light up upon sufficient provocation. In a paper on osteomyelitis which the writer read before the Denver County Medical Society in 1906 three cases of osteomyelitis of the femur were cited in which the *x*-ray located the abscess cavity in the shaft of the bone several inches from the knee joint although the pain was referred to this joint in each case.

The characteristic changes on the *x*-ray plate in a typical case of osteomyelitis consist in a marked proliferation of the periosteum and cortex of the bone in the neighborhood of the focus of infection, with a change in the arrangement of the normal striæ of the cortex or an interruption of the fibers, or grain, so to speak, of the bone. If abscess cavities are present in the medulla, they are indicated by circumscribed areas of greater translucency than normal. For the detection of the extent and locality of the disease it is necessary that plates be made from both the anteroposterior and lateral aspects.

The presence of proliferating periostitis and ostitis upon the *x*-ray plate differentiates osteomyelitis from sarcoma, tuberculosis, or bone cysts. Furthermore, by the *x*-ray plate we can determine whether we are dealing with a case of periostitis, whether the lesion is confined to the cortex, or whether the medulla of the bone is involved, and, a point of great importance to the surgeon, the extent, location, and number of abscess cavities can be definitely located.

Case II.—Man, aged 30. Osteomyelitis of the humerus with clinical manifestations strongly suggestive of sarcoma. Patient referred by Dr. L. E. Lemen. The arm was much swollen, not tender to pressure, but a dense infiltration of all the soft parts of the arm was present suggesting the strong possibility of an extensive enlargement of the shaft of the humerus. This condition had been increasing for several months, until at the time of the examination the arm from its size and the pain present was practically useless. The *x*-ray plate showed that the brawny condition of the arm was due to an infiltration of the muscles and tissues about the bone and that there were three distinct abscess cavities in the shaft of the bone, one below the surgical neck of the humerus, a second about the middle of the shaft, and a third near the lower end of the humerus. *Diagnosis:* Osteomyelitis with abscess cavities.

At operation the *x*-ray findings were verified.

Case III.—Osteomyelitis with deformity simulating Colles' fracture.

Female, aged 5. This case was referred by Dr. Parker, a previous diagnosis of fracture of the lower end of the radius having been made on account of the swelling that resembled a silver fork deformity. The *x*-ray plate showed an abscess of the lower end of the radius with destruction of bone substance. Complete recovery followed drainage of the abscess cavity.

Case IV.—Female, aged 9. Sent to Colorado with the diagnosis of tuberculosis of the metatarsus of the right foot. Patient referred for *x*-ray examination by Dr. C. A. Powers. The entire shaft of the second metatarsal bone was shown to be diseased with an enlargement of the bone and areas of softening. From the appearance of the plate, tuberculosis of the bone was excluded and a diagnosis made of an ostitis with areas of softening and the probability of malignancy was suggested. Infiltration of the soft tissues in the region of the affected bone was present. The metatarsal bone was removed and a microscopical diagnosis rendered of small-celled sarcoma. Amputation at the lower third of the leg was performed shortly after the pathologist's report was received.

From my experience, in the interpretation of bone disease from the *x*-ray plate, it has been found of the utmost importance to regard the amount of proliferative periostitis and ostitis present, and in any case where there is an unsymmetrical enlargement of the bone with areas of softening without an accompanying proliferative periostitis and ostitis, the strong probability of a malignant disease is always to be considered. In the diagnosis of sarcoma at a later stage, the pushing out of the growth from the cortex through the periosteum is diagnostic, yet I have seen several cases of sarcoma of the bones in which the entire growth was encapsulated with layers of thickened periosteum. One of these was a mixed-celled sarcoma of the lower end of the femur in which egg shell crackling was well marked. This case was reported in the *Denver Medical Times* in 1907.

There is probably no class of cases in which more frequent mistakes have been made in diagnosis than in that grouped under the head of arthritis deformans. Many of these cases are treated every year for rheumatism, are sent to various medicinal springs in the hope that the water and baths will cure the infirmity, and while the correct diagnosis is not made and suitable treatment applied the osteophytes are increasing in size and number, the joints becoming more stiff, the tendons, ligaments, and muscles losing their elasticity and becoming contracted so that by the time a correct diagnosis is made the patient has become greatly crippled, and

is in a condition in which the hope of a cure is entirely dispelled and only palliative treatment remains. Attention was called by the writer to the importance of an early *x*-ray examination in these conditions in a paper entitled, "The *X*-Ray as a Valuable Aid in the Diagnosis of Osteoarthritis," read before the Denver County Society in 1906. In osteoarthritis one or several joints may be involved, and while the exciting cause in many cases is difficult to ascertain, traumatism seems to play an important factor in some cases, particularly in the hip joint.

Case V.—Man, aged 40. Referred for diagnosis by Dr. Arneill. Patient had complained of stiffness and soreness in the back for some years, had consulted several doctors who regarded the case as rheumatism and had given treatment accordingly. The patient, of course, obtained no relief from the medication; the stiffness in his back became worse until he was practically incapacitated for work. The *x*-ray examination showed a well organized bony exudate between the upper lumbar vertebræ thoroughly welding them together. *Diagnosis:* Hypertrophic osteoarthritis. If the correct diagnosis had been made much earlier, this man's condition certainly could have been made more comfortable and the advance of the disease probably checked by the application of proper mechanical supports. These cases of hypertrophic osteoarthritis of the spine are comparatively common.

The atrophic form of osteoarthritis is frequently seen in old people and the ravages of the disease are marked by their distorted and almost useless hands and fingers. The diagnosis is easily made by the *x*-ray for the destructive process of bone is well shown on the plate and is easily differentiated from so-called gouty deposits or tophi about the joints, for in the latter condition there is no destruction of bone and the deposits are confined to the soft tissues.

In the destructive form of osteoarthritis associated with tabes the characteristic destructive changes in the bones with a probable subluxation of the joint are characteristically shown upon the *x*-ray plate. This disease is most frequently manifested in the knee joints, where it is commonly known as Charcot's knee. I have plates of two different cases in which I was able to make the diagnosis of a tabetic destructive osteoarthritis in the lower lumbar vertebræ. This condition in the spine is very rare, but few cases having ever been reported, and is known as Charcot's spine. In connection with hypertrophic osteoarthritis attention is called to a condition with which it may be confused, both clinically and upon the *x*-ray plate, namely exostoses.

Case VI.—Man, aged 55, referred by Dr. Richards. Patient had had considerable pain in the back which had persisted more or less since an injury to his back twenty-five years previous. In addition to the pain above mentioned, when he assumed certain positions, such as straightening the spine after bending forward or straightening the spine after bending laterally, he was occasionally seized with a severe pain or cramp which was of such severity as to render him helpless for a few minutes. An *x*-ray examination of the spine showed a well marked exostosis in the shape of a horn springing from the side of the body of the third lumbar vertebra. The differential diagnosis in this case from hypertrophic osteoarthritis was made from the fact that the growth was single, was well defined with a broad base blending with the vertebra, and the shadow was that cast by dense bone of normal structure and did not spring from the joint surface.

Bone Tuberculosis.—It is the general opinion that the *x*-ray cannot detect changes in the bone before the diagnosis can be made by clinical signs. In the hands of an expert diagnostician this is probably correct. If, however, we accept the theory that tuberculosis of the joints practically always starts in the epiphyses and that the synovia are affected secondarily either with or without breaking down of the bone substance, a carefully taken and accurately interpreted *x*-ray plate should show destructive changes in the bone trabeculæ, if present, before the synovia becomes infected. Such a destructive process or the extent of it cannot be determined clinically.

It is granted that a bone infection may exist in its incipiency before any change in the texture of the bone has taken place; in this case only normal shadows will appear upon the plate, but with a thorough knowledge of the normal shadow cast by the parts in question we should be able to detect a very slight change in the texture of the bone, as soon as a destructive process starts. It is not the fault of the *x*-ray that these changes are not shown but rather that of the interpreter who, in many cases, fails to attach the proper significance to a slight deviation from the normal shadow.

If we accept the theory that tuberculosis of joints affects primarily the synovia and secondarily the bones, we must admit that the *x*-ray cannot show the pathological changes in these soft structures until after a considerable lapse of time and that secondary destructive processes are present in the bone. It is of extreme importance in every case that an *x*-ray plate be made of both the normal and suspected joints, for in this way we may be able to detect a very slight change, not merely in the bone texture, but in the relative size of the bones, as atrophy of the femur takes place comparatively early in a tuberculous hip and should be given its proper interpretation. The writer has been able to make a correct diagnosis in tuberculous hips by contrasting the relative position of the normal and suspected heads of the femur to the acetabulum before any other signs were apparent upon the plate. In the suspected hip the head of the femur is likely to be drawn closer within the acetabulum than normal, due to the contraction of the muscles giving the head and neck of the femur an unnatural position to the acetabulum; again, a peculiar haziness about the shadows of the joint should always be looked for, and, if present, should be regarded as suggestive of a pathological joint.

Spasm is the first sign clinically in any inflamed joint, and yet how often is this danger signal completely overlooked or not given its proper interpretation by the general practitioner. Not infrequently cases are seen that have been treated by the general practitioner for rheumatism for quite a period of time and an *x*-ray examination shows a destructive process well established in the bone. Even if the *x*-ray as interpreted at the present day does not disclose minute pathological changes in the bones forming the joint until after the diagnosis can be made clinically, it is of great value in recording the first focus that appears, and in noting, from time to time, the progress of the disease or in showing

when bone resolution is becoming established. The appearance of a tuberculous focus is characterized by a greater translucency of the bone at this point, due to the absorption of the lime salts with partial or complete interruption of the normal striæ and an absence of any constructive bone process about the focus or the cortex of the bone.

CASE VII.—Female, aged 6 years. Had been treated for rheumatism of the right hip for three months, before consulting Dr. Fosdick Jones, who referred her for an *x*-ray examination. The plate showed the epiphysis of the head of the femur normal but disclosed several small foci with loss of bone substance in the rim of the acetabulum. *Diagnosis:* Primary tuberculosis of the acetabulum.

Syphilis of the bones attacks, primarily, the periosteum and later encroaches upon the cortex, causing nodosities or small cavities. The *x*-ray plate discloses this condition very accurately, and nodosities or small cavities in the cortex, with a thickened periosteum are diagnostic of syphilis. Occasionally a gumma develops in the spongy portion of the bone and may give rise to no clinical symptoms. The appearance on the *x*-ray plate closely resembles tuberculosis.

Bone cysts are often difficult to differentiate clinically from myelogenous sarcoma. Pain in bone cysts, however, is apt to be much less than in sarcoma. This diagnosis is most accurately made through the agency of the *x*-ray, which shows a marked difference between the two conditions. Bone cysts are always within the periosteum, and show a symmetrical enlargement of the bone with a uniform thinning and expansion of the cortex enclosing one or more translucent areas. In myelogenous sarcoma the growth is commonly seen pushing through the periosteum in an irregular manner. The normal striæ have disappeared and the whole mass has a hazy or blurred appearance. In periosteal sarcoma fine spicules of bone are seen radiating from the periosteum with translucent areas marking the site of bone involvement.

In the Roentgen ray we are employing an agent which for several years has demonstrated successfully its ability to depict upon the sensitized plate minute changes in the texture of the bones, and it is only since we have acquired by experience the ability to interpret correctly the meaning of these changes, as well as the changes from the normal in other structures of the body, that we are in a position to realize the great importance in diagnosis to the profession of the discovery of Roentgen.

726 FOURTEENTH STREET.

PHYSICAL THERAPEUTICS IN THE MEDICAL PRESS.*

BY MARY L. H. ARNOLD SNOW, M.D.,

NEW YORK.

THE medical press in this age of progress and exhaustive scientific research should be the beacon light of the busy practitioner, preventing him from running on the rocks and wrecking his lifeboat. At no time in the world's history, as during the last decade, has the medical profession made such advancement, not only in the study and cure of disease, but in its prevention and the preservation of health, and as a natural sequence the profession asks that the medical press shall keep abreast of the times if it desires the patronage of those whose highest and most pleasurable duty it is to heal the sick and whose debt to their patients demands knowledge of all measures that will lessen or relieve the ills of humanity.

In response, the medical press that of old was characterized as some one has aptly expressed it by "doubt, pessimism, and intolerance," has been obliged to remove the shutters from its windows and let in a flood of sunlight of knowledge. A recent writer sounded the tocsin of war against the journalism of the past when he said: "With all the earnestness at my command, I want to insist that it is time to take account of stock to get our scientific, ethical, and commercial bearings, and set out for the future with confidence, trust, and steadfast purpose." It is the journal edited along such lines that brings hope to the progressive insurgent in medicine. Its policy is broadmindedness and tolerance. It is a missionary in the field of medicine and represents neither man nor money power, but independent democracy. Independent in that it believes in equal rights for all, in that merit warrants success, and in that it reserves the right to be conservative when relief of human ills demand it. Dr. Butler's terse remarks are very apropos: "Truth, courage, independence, liberality, should characterize the medical journal—more charity and less dogmatism, a recognition of the right of every sentient creature to his own opinion. So long as it boycotts those who dissent from its dogma it will breed hypocrites and humbugs."

Contributions to such journals are accepted on their intrinsic worth whether treating of drug therapy, surgery or physical measures. All sources of information are their fountain heads of knowledge. Each subject, be it old or new, is a mine. Lack of selective instinct lowers the grade of medical journalism: the editor, not being conversant with certain subjects, either refuses papers from those whose experience makes them advocate special measures from a wish to disseminate their knowledge, or he accepts inferior articles of little practical value to the reader on the subject of which they treat.

The trend of modern medicine, owing to the materialistic time in which we live, is away from that of a cabalistic nature, away from the mysterious, the empirical, looking solely for cause and effect. The result is that never were the various narrow pathies and cults so well patronized as now, so that the old-time practitioner with his saddle bag and drugs is fast becoming a picture of the past. It is to meet this demand of the public, looking more and more into the cause and the prevention of disease as well as its cure, that the medical press should devote more time, thought, and space to many subjects to which little or no space has been given in the past, for not only are the subjects being investigated and used by the public, through either ethical or nonethical channels, but they give results obtainable in no other way.

Physical therapeutics is the treatment of disease by those natural measures in contradistinction to drugs which assist or correct nature in her efforts to restore a normal condition. It includes electricity, radium, light and heat, hydrotherapy, mechanotherapy, and diet.

Electricity is probably one of the most potent agents in the hands of man. It comprises the constant, continuous, or galvanic current; the induced, interrupted, or faradic current; the static, the high-

*Read before the American Medical Editors' Association in Los Angeles, Cal., June 26, 1911.

frequency, and the sinusoidal currents, as well as being the source of the *x*-ray.

In past times the *constant and induced currents* were used largely in diagnosis. The employment of the constant or galvanic current with its polar characteristics having a sedative, analgesic, styptic, or destructive property, is indicated in the treatment of reflex troubles, in affections requiring a mild stimulant; in conditions suitable for styptic electrolytic action as new growths and hemorrhages; for destructive action on cicatrices, warts, epithelial hypertrophies, connective tissue or bony or cartilaginous growths such as fibroma, osteoma, enchondroma, etc. Metallic electrolysis, so ably expounded by Massey, invades the field of surgery and gynecology; passive congestions, local sepsis and cancer, operable or inoperable, find it a most useful agent. Phoresis is a vehicle for drug therapy and is of value as a means of anesthesia in minor surgery, in the practice of medicine, and in dentistry. The induced or faradic current is a mild stimulant.

The static current, yielding at least twenty different modalities, is replete with possibilities. The recognition of its therapeutic indications, application, and value is as yet in its infancy. Its effect on stasis alone is one worthy of widespread attention from the medical profession. When a sprain can be cured, not simply relieved, in three treatments with a modality that can do no harm even in the hands of a novice, suffering demands investigation of its claims. Its use is indicated in all inflammatory conditions, except those of an infectious nature—sprains, bruises, arthritis, myositis, gout, synovitis, rheumatoid arthritis, and the painful neuroses such as sciatica and neuritis. Its great tonic and metabolic action marks its indication in the general treatment of paralysis, neurasthenia, hysteria, tuberculosis, and asthenic conditions in general. Its power to relieve tension makes it valuable in the treatment of pathological states characterized by muscular contractions. In dermatology it is most satisfactorily used as the wave current, brush discharge, or the high-potential discharges, which locally render microorganisms inert. It stimulates normal metabolism locally, lessens edema and congestion, relieves pain and itching, and promotes secretory activity. It will be indispensable when recognized in the field of the neurologist, surgeon, dermatologist, internist, gynecologist, and genitourinary specialist. It is an agent unrivaled in the treatment of the above conditions.

The static induced current is a most powerful muscle exerciser when of low frequency, and is indicated in conditions requiring special muscular activity to overcome atrophy. Its possibilities far exceed those of the induced or faradic current.

High-potential currents with the vacuum tube are stimulating, rubefacient, antizymotic, and analgesic, affecting metabolism by local heat production, restoration of secretion, and when direct from the machine relieve stasis with its consequent relief of pain.

High-frequency currents with their great thermic action call for pronounced recognition in the treatment of high blood pressure and its accompanying conditions, as well as in the management of infectious processes which heretofore have been treated only by the knife.

The sinusoidal current is like the faradic in action. It is a muscle exerciser, analgesic, improves nutrition, and is useful in connection with spondylotherapy.

The mystical *x*-ray has been honored with greater attention by the medical press than any of the other electric modalities, as it early became the surgeon's spectacles, and the existence of a surgical age demands the acknowledgment in the press of anything novel pertaining to the subject. Diagnostically and therapeutically its field is almost limitless. In radiography, it reveals the hidden. In radiotheraphy, owing to its marked inhibitory action, it is an agent employed to treat abnormal growths such as sarcoma, carcinoma, and fibroma. In the treatment of fibroids in particular, it robs the surgeon of many a case. In the treatment of skin diseases it is a remedy *par excellence*. Owing to its daring use by hero enthusiasts and those who have applied it in an unscientific manner and suffered in consequence, many of the profession at present hesitate even to consider its employment. The medical press is the agency to right matters here.

Radiant light and heat represent the employment of the electric arc, the incandescent light, the mercury vapor lamp, the actinolite, the solar arc lamp, the Finsen apparatus, the Minin blue light, incandescent bath cabinets, and arc light cabinets.

Physiologically considered, radiant light and heat have an actinic as well as a thermic action. They induce hyperemia, allay and cure inflammation, and relieve acute and infectious symptoms. They have a place in the treatment of atonic conditions, states of faulty metabolism, inflammatory diseases such as otitis media, cystitis, appendicitis, phlebitis, and adenitis, as also some dermatological affections.

To obtain convective heat, moist or dry, the use of the poultice, hot-water bag, Russian bath, hot-water bath, hot douche, local and body hot-air apparatus, hot-box, and Turkish bath is indicated. The value of hot water, as in the use of the hot douche and hot-water bag, is known to every practitioner, but if the therapeutic action of radiant light and heat and of convective heat was more widely understood, the practitioner would as quickly adopt the most approved and improved apparatus for the production of heat as he abandoned the "one hoss shay" for the modern automobile.

Convective heat is indicated in the treatment of tonsillitis, felons, mastoiditis, inflammatory conditions of the pleura and abdomen, joint inflammations and sepsis, where it is the treatment of choice. Many an arm and leg might have been saved had the physician in charge acted with a full knowledge of the value of hot-air treatment. It also invades the domain of the surgeon, laryngologist, internist, dermatologist, and gynecologist.

Hydrotherapy includes the study of the action of heat and cold and other uses of water of varying temperatures, internally and externally. Temperature determines its physical actions of relaxation or contraction, stimulation or depression or sedation. Therapeutically it is used to advantage in fevers, alimentary tract disturbances, respiratory affections, functional nervous diseases, and in fact in the treatment of all conditions calling for better elimination.

Mechanotherapy indicates manual or instrumental manipulation of the parts of the human body. As such it includes massage, therapeutic exercise, and mechanical vibration. Ling and his followers and Weir-Mitchell and his school long ago demonstrated the efficiency of the first named, and exercise in this country owes its scientific progressiveness to such able members of the profession

as Drs. Savage and Sargent. Activity is essential to well being, but to obtain results exercise must be prescribed from a physiological basis for any pathological condition.

Mechanical vibration is an agent whose value as a diagnostic measure is not exceeded even by the stethoscope and it needs but to be more generally known to be fully appreciated. It has chemical as well as thermal, reflex, metabolic, and mechanical actions. Its therapeutic action thus covers the field not only of massage but of osteopathy as well. In the hands of the general practitioner, for this reason, it has indeed become a most powerful weapon against much current quackery.

Dietetics is a study of foods as regards their elements, properties, nutritive value, purity, and selectiveness in the treatment of disease in order to establish and maintain normal balance. It is a very important study not only in relation to diseases of the alimentary tract and all conditions pertaining to metabolism, but also in connection with high blood pressure, a subject of interest to all. Some of us eat to live, while others live to eat. To those who belong to either class the study of dietetics is of prime importance. To one class it tells what is best to select in order to keep well, while to the other it points the way to keep well in spite of their indulgent proclivities.

The above is an outline as to the possibilities of the subjects for which I appeal to you for greater recognition. The results obtained by their use speak to the laity, who in turn demand more and more from their physicians a knowledge of drugless methods if their patronage is to be retained.

Measures of such wide applicability and fields of usefulness should be made more generally known to the surgeon, neurologist, laryngologist, internist, gynecologist, dermatologist, and genitourinary specialist; and such an advance can come about honestly only through the medical press, a power that inspires and influences—an educator—the pulse of scientific progress in the medical world.

329 West Fifty-Seventh Street.

RADIOACTIVE WATERS IN THE TREATMENT OF GOUT.

By A. C. BURNHAM, M.D.,

NEW YORK.

The marked and indisputable success of the spa treatment of gout and rheumatism has long been attributed to the strict régime and favorable climatic conditions of the individual spas. Following the discovery of radium it was found that many of these waters possessed a distinct property of radioactivity, which added to their therapeutic significance an element heretofore entirely disregarded. In Germany the attempt has been made to determine the therapeutic value of this new agent (especially in the treatment of rheumatism and gout) with sufficient success to warrant a thorough and systematic investigation of the entire subject in this country.

In 1905 Neusser[1] reported favorable results in two cases from the use of radioactive waters applied locally. In 1908 Dantwitz,[2] working in Neusser's clinic, reported further good results from the use of radioactive baths in joint affections and neuralgias. Since 1908 numerous investigators (Laquer, Nagelschmidt, Riedel, His, and others) have reported favorable results from the use of radioactive waters in a variety of conditions. Today there is no question of the activity and value of radium emanations. The discussion resolves itself into the question: When and where is such a therapeutic agent indicated?

The radium emanations have been used in a variety of pathological conditions with varying degrees of success, but the results obtained in gout have been so striking, and so in accord with the laboratory finding, that they warrant further confirmation. Radium itself is so expensive that it is beyond the reach of the practitioner. The radioactive waters are easily obtainable, and are in such a form that they may be freely prescribed.

Preparation: Radioactive water may be obtained by one of the following methods: (1) From natural radioactive springs. This is naturally a difficult matter, as the springs in America have not been tested for this property to any extent, and furthermore because the radioactive content of these waters is usually insignificant. (2) By the use of radium salts, usually radium bromide, in tablet or powder form, dissolved in water. (3) By the use of artificially prepared and tested radioactive water. The last method is probably the best because it is the most practical, the least variable, and most reliable of the three methods.

Dosage: The strength of the radium emanations is measured in units. The Mache-unit is the one commonly used; it is equivalent to 116 volt-units. The usual daily dose is 1,000 units, which may be increased up to 5,000 or even 10,000 units. Much larger quantities have been given without bad effects. The baths usually contain from 5,000 to 10,000 units.

Administration: The radium emanations may be administered, in gout, by one or more of the following methods: (1) Internally, in doses of 1,000 to 2,000 units per day, beginning with a small dose, 500 units, and gradually increasing to the desired maximum dose. It should be given in small doses at intervals during the day rather than one large dose. (2) Subcutaneous or intravenous injection in doses of 300 to 1,000 units per day. (3) Baths containing 1,000 to 5,000 units. As the good effects from these baths are due to the inhalation of the emanations, the patient should be completely enclosed in a bath cabinet, and the baths should last from twenty minutes to an hour or more, the patient inhaling the emanations during this period. One or more baths may be given daily, care being taken not to overtax the strength of the patient. (4) Inhalation. This method requires: (a) An apparatus which liberates the emanations: (b) a closed compartment capable of permitting the patient to move freely, to read, eat, etc.; (c) an apparatus to supply the required oxygen; (d) an apparatus to remove the excess of CO_2; (e) an apparatus to remove the excess moisture from the air. His has such an apparatus installed in the Charité Hospital in Berlin.[3] The patient is required to remain in this compartment for several hours daily. The results from this form of administration are good, but necessarily it is expensive and not at present applicable in private practice. (5) Local applications. Compresses and clay may be used as local applications. They have been especially recommended for the relief of pain. Raw surfaces and mucous membranes have been sprayed and washed with the radioactive water. Body cavities, the nose, throat, stomach, rectum, bladder, etc., may be douched with saline solution to which radioactive water has been added.

Action: The action of the radioactive waters in gout is not clearly understood. Certain facts have, however, been proven, and these facts are so in keeping with our present theories of gout that the value of the emanations seems almost beyond discussion. Gudzent, working in His' clinic, found in the blood of gouty patients two forms of monosodium urate. One of these is stable and relatively insoluble, while the other is unstable and much more easily dissolved. He demonstrated further that the insoluble form was changed into the soluble form, in test-tube experiments, when exposed to the influence of one of the decomposition rays of radium, the "β-rays." If a solution of monosodium urate is injected beneath the skin of a rabbit there results an active infiltration of leucocytes with all signs of severe inflammation. This inflammatory reaction is followed by necrosis and the disappearance of the urate in from twelve to fourteen days. The urate is taken up and carried away through the phagocytic action of the leucocytes. Now, if the process is carried on under the influence of radium emanations the result is different. The leucocytic infiltration is entirely absent and the inflammatory reaction is much less marked. On the other hand, the necrosis is much more extensive. At the same time, in spite of the absence of phagocytosis, the tophus disappears.* Therefore we are justified in the conclusion that the radium emanations dissolve and break up monosodium urates, both *in vitro* and in the living organism. The increased necrosis is due to the fact that the monosodium urate in solution is an intense tissue poison.† The uric acid metabolism in gouty patients shows a decided change under the influence of the emanation treatment. Gudzent‡ found that the uric acid entirely disappeared from the blood in thirteen out of fourteen cases examined before and after treatment. Furthermore, there was a noticeable diminution in the size of the tophi during treatment. If a person, on a purin-free diet, be given a certain amount of uric acid about 50 per cent. of it appears in the urine. This occurs whether the subject be healthy or suffering from gout. The difference in the action is that in health this excretion takes place in twenty-four hours, whereas in gout it requires three or four days or longer. This reaction is almost pathognomonic of gout and is known as the "delayed excretion of exogenous purin." After emanation treatment this characteristic sign of gout is absent and the organism apparently reacts to exogenous purin in a normal manner. Lowenthal found in one patient under emanation treatment a marked increase in the uric acid excretion: before treatment it was 0.274 gram; during treatment it was 0.513 gram. At the end of this treatment the patient was tested with large doses of purin bodies and the excretion occurred normally, although there had been a distinct retardation in the excretion of exogenous purins before emanation treatment was begun. The general metabolism is said to be increased during treatment. This question is, as yet, undecided.

Three theories have been advanced to account for the disappearance of the uric acid in the blood: (1) Activation of the ferments. This causes the oxidation of the uric acid and its further disintegration into CO_2 and ammonia. (2) Direct action on uric acid. In this theory the emanations are supposed to act directly on the uric acid, causing its solution and disintegration. (3) Increased activity of the kidneys, which, consequently, excrete the superfluous uric acid from the blood. The first theory is to-day the most widely accepted one, although the other theories may also act to complete the process.

Excretion: The emanations are partly broken up in the body, but the larger part is excreted through the lungs regardless of the method of administration. This excretion takes place most rapidly when the inhalation or injection method is followed, and less rapidly by the other methods. When given *per os* the emanations continue to be excreted for three or four hours or slightly longer. Excretion takes place to a slight extent through the kidneys, occurring about one hour after a large dose is given. Some observers have not been able to find any in the urine even after fairly large doses. The feces regularly show a small degree of radioactivity after the emanations have been given internally. The rapidity of excretion when the emanations are given by inhalation suggests the futility of expecting prolonged action by this method unless it can be carried out over long periods. When given by mouth the action, in consequence of the longer period of excretion, may be made almost constant by giving small doses at frequent intervals (three to five times daily).

Results of treatment: It is too early to outline definitely the types of cases in which we may expect the most benefit, and at what stage the most improvement may be expected, but, in general, it may be said that the best results may be looked for in those cases in which the gouty process is not too far advanced. Little improvement can be expected in the old, deformed joints where tissue changes have become permanent and where the patient is suffering not so much from the gout itself as from the erosions and deformities of the joints. During the early part of the treatment the patient notices a distinct increase in the symptoms. This increase has been noted for many years in patients undergoing treatment at certain spas. The absence of this reaction or the severity of the same has no influence on the prognosis, many patients getting entirely well who have shown no reaction at all, and *vice versa*. Improvement begins usually after two or three weeks, except in older and weaker patients, in whom it is sometimes delayed until the sixth or seventh week. In all cases the treatment should be continued at least four weeks.

I have been able to collect fifty cases of gout treated by means of radium emanations. These cases were in the main reported in the German literature. Of these cases less than 20 per cent. were reported unimproved, and in only one case was the patient distinctly worse at the end of the treatment. The percentage of cures is no mark, however, of the enthusiasm of the observers. In almost every case in which improvement was expected, that is, in young individuals without marked changes in the joints and kidneys, the result was most favorable.

Conclusions.

1. We have, in radioactive waters, a heretofore unrecognized therapeutic agent of real clinical value.

2. Both *in vitro* and in the human body the radioactive waters have an indisputable action on the purins.

3. In gout the action is in many cases, if not in every case, a favorable one.

4. Further study of the radioactive waters, both from a clinical and from a scientific standpoint, is most desirable, and further investigation will no doubt show their value, not only in gout and the allied diseases, but in many cases of neuralgia, muscular rheumatism, and other diseases of like nature.

A FATAL CASE OF BISMUTH PASTE POISON.

By LEONARD W. ELY, M.D.,
DENVER, COLO.

A number of fatalities have occurred from the use of bismuth paste, but Dr. Beck,* the author of this treatment, states that in doses up to 100 grams the paste is quite innocuous. I have had rather a wide experience with bismuth paste in tuberculous sinuses, and have strongly advocated its use.† Indeed, until its introduction an infected abscess from Pott's disease was thought an invariably fatal complication. It should be recognized, however, that bismuth paste has its dangers, and if we can find an entirely innocuous substance to replace it, we shall do well to make the change.

The case I would report is as follows:

G., 3 years old. Diagnosis: Caries spinalis thoracis. Duration of disease, about one year. The case was a typical one, with a well-marked kyphosis and a freely discharging sinus in the right lumbar region, which ensued on an abscess. This abscess was opened April 12, 1911.

July 7, 1911. An injection was made into the sinus, consisting of the regular bismuth paste mixture, 1 part bismuth subnitrate to 2 parts vaseline. July 9. A sharp rise in temperature, to 103° F., followed the injection.

August 24. The temperature soon subsided, and the child did well thereafter. An injection of about 2 ounces of the paste was made to-day.

August 26. A sharp febrile reaction again followed the injection, reaching 103 F°.

September 15. The temperature soon subsided, and has since run between 97.5° and 99.6°. A skiagram shows involvement of the vertebræ. About 2 ounces of the paste were injected to-day. Sept. 19. The injection was followed by the usual rise in temperature, which is slowly subsiding.

September 30. The abscess is almost healed. A drop or two of pus occasionally exudes. The patient has a blackish discoloration on one side of her tongue, but seems in fairly good condition.

October 5. The child has been vomiting constantly, has lost weight steadily, can keep nothing on her stomach, and is very restless. October 8. 8 c.c. of olive oil was injected into the sinuses. October 9. Rectal feeding begun and continued to the end. The temperature does not run above 100° F.

October 14. The patient is growing steadily worse, and refuses all food. Ulcers on both sides of the mouth, between the cheek and alveolar process, are spreading rapidly. Some little discharge of bismuth followed the injection yesterday of 8 c.c. of olive oil. The temperature is practically normal, and pulse runs about 120-130. The mouth is dry and brown. The child is emaciated, sleepless, and tosses her head about. The blackness of the tongue has persisted and increased.

October 17. Two bloody stools. Exitus.

*Emil G. Beck: "The Surgical Treatment of Tuberculous Sinuses and Their Prevention," Transactions of the Sixth International Congress on Tuberculosis, 1908.

†*American Journal of Surgery*, January, 1910.

Appendicitis and Angina.—A. Krogius notes in an analysis of 1,000 cases of appendicitis operated upon in the surgical clinic of Helsingfors during the period from 1901 to 1908 that there was no evidence of epidemicity; that no relationship could be discerned between appendicitis on the one hand and influenza and enteritis on the other; but that the figures and curves showed an etiological relationship between appendicitis and angina.—*Von Langenbeck's Archiv.*

Frequency and Pathogeny of Crural Hernia in Children. Case in a Child of Ten Years.—H. L. Rocher and M. Dantin state that crural hernia exists in children, although rare. Its maximum frequency is between the ages of ten and twelve years. Its pathogeny is allied to an anomaly of the internal part of the crural ring, a dysplasia of the crural septum, or ligament of Gimbernat, or to the presence of a preformed cul-de-sac. The author's theory of its occurrence gives the origin to a failure of the parietal region of the abdominal wall, while that of Murray gives it a serous origin. The author believes that both of these theories have their application in certain cases. They have a common point, namely, congenitality of the lesions. Sex has not a marked effect on the occurrence of this variety of hernia. These hernias are generally single, rarely double. They generally occur gradually, and are not recognized early in their occurrence. The author gives histories of two cases in which the hernia was of considerable size and appeared gradually.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux.*

Vaccinotherapy by Irradiated Vaccines.—Maurice Renaud presents a biological study of typhoid vaccine. His vaccines are prepared from cultures of the bacillus of Eberth isolated from the blood of a typhoid patient whose disease was demonstrated at autopsy to be typhoid. Its virulence is such as to kill animals in twenty hours after injection of 7 to 8 milligrams. Forty-hour cultures on gelose are emulsified in physiological salt solution; the emulsion is thus exposed to the irradiation of a quartz lamp for 30 minutes. After this treatment the bacilli have entirely lost their virulence; they are incapable of reproduction and cultures remain sterile. They lose their motility, but undergo no other changes in form. This vaccine may be employed without fear or precautions. It is very easily absorbed when injected under the skin. The local reaction is slight and appears after a few hours. The author compares the effects of inoculation of this vaccine and of virus. The injection of vaccine causes but a short reaction; with an equal dose of virus the reactive period is the same. With both there is a primary period of excitation analogous to that of infections of acute beginning, and this excitation arouses the protective mechanism of the body. The author believes that the microbic products, pure and unmodified, are less toxic than has been supposed, which accounts for the larger doses possible. These irradiated vaccines cause an extremely sudden and brief reaction which never causes grave symptoms and they are eliminated rapidly and completely. Such inoculation presents no dangers, and no risks are incurred. Death is never caused by the intoxication. It causes an immunity and the appearance in the blood of antibodies; large doses may be used to obtain immunization. Each new injection increased the bactericidal properties of the blood. More than 40 typhoid patients were inoculated.—*La Presse Médicale.*

HABIT, SYMPTOMS, AND DISEASE.

EVERY physician is conversant with the affections of the nervous system which are the manifestations of some unusual and long-continued habit. They are exemplified by the "habit spasms," simulating chorea, in children, and by the varied group of "ties" in adults of neuropathic constitution. These affections involve the nervous mechanism of the body, and it does not seem strange that habit should lead to perversion of function in that mechanism. Most physicians, however, would be surprised to be told that a similar perversion of function, because of habit, may occur, and frequently does occur, in other mechanisms and tissues of the body; yet this is the text of a recent address delivered before the Medical Research Club of the University of Pittsburgh by the well-known Canadian pathologist, J. George Adami ("International Clinics," Twentieth Series, Vol. IV).

Adami tells of a patient cured of incipient tuberculosis, who continued to cough and to bring up an excessive amount of mucoid expectoration long after all other symptoms and signs of the disease had disappeared, the reality of the cure being evidenced by a gain of fifty pounds in weight. The cough could be explained easily enough—it was of that nervous type engendered by habit and seen very frequently in such conditions. There seemed to be no reason, however, why habit should not explain the increased amount of expectoration, habit this time affecting not nervous function, but secreting tissues or individual cells. As soon as this explanation occurred to Dr. Adami numerous similar phenomena were easily explained, among them chronic nasopharyngeal discharge after infections of the nasopharynx, continued and excessive production of saliva after a single salivating dose of mercury in a susceptible individual, obstinate diarrheas after dysenteric affections, and the like.

In generalizing from these and other observations Adami points out that there are three orders of cell activities: (1) those determined by nervous stimulation, which may be termed *neurogenic*; (2) those determined by direct stimulus of the individual cells by anything modifying their immediate environment—the *environmental*, and (3) the *automatic* activities, namely, which proceed in spite of absence of sustained stimuli of the first two orders. The automatic activities are not independent of development: they are simply a continuation of activities initiated by single or repeated nervous or environmental stimuli, and they continue after the cessation of the stimulation. The cells thus develop "habits of activity" and these habits go far in explaining various manifestations of life in health and in disease.

A postulate of this theory is the possibility of some altered or unusual activity of a group of cells under the stress of unusual environment; this altered activity may be transmitted by heredity to other cells, derived from the original group and thus lead to some quite unusual manifestation in the body. This postulate Adami cautiously applies to the possible explanation of the origin of cancer in some instances; cells active in some new direction may lose their original function and increase their simple vegetative powers, they "assume the habit of growth," and this may lead to the formation of a neoplasm.

Lack of space forbids further consideration of Adami's address; the original paper may, with profit, be consulted by workers in search of a stimulating presentation of old problems and of new explanations of the phenomena of disease.

DEGENERATION.

THE looseness with which the word degeneration is employed forms a serious obstacle to the proper appreciation of involutionary phenomena in the human species. It is often difficult to discriminate between involution and evolution. There should be a science of comparative involution, yet it would be very difficult to imagine such a phenomenon as degeneration in the animal kingdom as a whole. There is a so-called degeneration which is conterminous with death and infertility, and one with which longevity and fertility are not incompatible. There is a so-called degeneration associated with antisocial and criminal tendencies and one associated with diseased states, specially nervous and mental diseases; and the two types need not overlap. Degeneracy is constantly being confounded with heredity, and recent progress in our knowledge of the latter shows that much so-called degeneracy is purely a matter of remote inheritance, certain types of individual continuing to appear without any real deterioration of the stock as a whole. Degeneration may or may not be considered as atavistic, and it may or may not be brought in association with physical stigmata.

There seems to be little correspondence between the degeneration of races, of families, and of individuals. Degeneration can mean only that each succeeding generation is less fitted for existence than the one which preceded it, until the entire race or stock perishes. The numerous theories constantly advanced to account for the extinction of the old Greeks and Romans, the medieval Normans, etc., show how small is our real knowledge of these subjects. Climate, disease (especially malaria), constant warfare, luxury, race suicide, neglect of the soil, miscegenation with inferior races, and inability to breed with other races—these represent only a few of the theories advanced from time to time. It would seem that the expression "race regeneration" is a simple figure of

speech for race extinction, or that it represents a mere begging of the question. Evidences of degeneration may coincide with extinction, just as they occur when the race is flourishing or at an equilibrium. Degeneration in a family may simply mean extinction from very obvious causes or it may mean the continued reappearance of remote ancestral qualities augmented by unwise crossing, such as has often been recorded in royal families. Individual degeneracy in a sound stock suggests the familiar "black sheep," a subject best understood in connection with remote heredity. It must be borne in mind, however, that a new type of individual may develop in a perfectly sound stock as a so-called sport or freak.

At a recent meeting of the Deutsche Naturforscher und Aerzte (*Berliner klinische Wochenschrift*, October 30) Bumke read a paper on nervous degeneration as an entity, in which he insisted that so far from conducing to degeneracy the hereditary forces invariably tend to repair the damages sustained by individuals. In other words, heredity means regeneration. Diseases are not concentrated but diluted in succeeding generations. Some element like crossed heredity or consanguinity is necessary to prevail against this conservative force. Much socalled heredity is actually accounted for by injury to the germ plasm, such as occurs so readily from parental syphilis, alcoholism, tuberculosis, plumbism, etc.

STREPTOCOCCUS STRAINS.

When the remarkably favorable results of the use of diphtheria antitoxin became generally known, efforts were immediately made to produce sera for the treatment of other infections, notably those in which the streptococcus had been found and in which it was believed to be the causative factor. These conditions are numerous and differ widely in the clinical pictures which they present. Therefore, when antistreptococcic sera proved to be of little therapeutic value, the explanation was offered that these various diseases were caused by different varieties or strains of the organism.

Efforts to differentiate these strains were for a time unsuccessful. The appearance of the chain produced was proved to be due to the medium used, so that such names as *S. longus*, *S. brevis*, and *S. conglomeratus* were not justified by facts. The more recent advances in immunity also failed to furnish needed information since the various strains seemed to be related so closely that agglutination, anaphylactic, and complement fixation tests proved unsatisfactory. Schottmüller, however, grew the organisms on blood agar plates, and from the information so obtained was able to distinguish four strains: (1) *Streptococcus pathogenes* or *erysipelatos*, producing a wide hemolytic zone; (2) *S. viridans* or *mitior*, producing green pigment and a narrow hemolytic zone which differs somewhat in character from that of the pathogenes; (3) *S. saprophyticus* or *anhemolyticus*, producing no hemolysis; (4) *S. mucosus*, producing some green pigment and also a mucus-like material. *S. mucosus* resembles the pneumococcus in that it is soluble in bile salts and develops a capsule, so it is usually considered to be a strain of that organism. *S. saprophyticus* is found in nasal, buccal, and vaginal secretions and on the skin, and is generally nonpathogenic. *S. pathogenes* possesses high virulence for man and animals and has been isolated from patients suffering from severe diseases, such as rheumatism, erysipelas, scarlet fever, and puerperal sepsis. *S. viridans*, on the other hand, exhibits a much lower grade of virulence and is found in the milder conditions, as chronic rhinitis and bronchitis, and chronic endocarditis.

Naturally, the claim was made that these varieties expressed merely the reaction of the single organism to changes in environment, but Le Blanc (*Centralbl. f. Bakt.*, etc., I Abt. Orig., Bd. 61, H. 1 & 2, p. 68) and Rolly (*Idem*, p. 86) have shown that none of the alleged instances of transformation from one type into another can be substantiated. Although grown for variable lengths of time on such media as saliva, milk, and horse serum, and subjected to changed physical surroundings, in each case the culture has retained the characteristics of its strain. It is of course probable that these divisions, now recognized as separate strains, will be further differentiated following improvements in technique. This probability is strengthened by the experience which has been obtained from the use of vaccines. The results following autogenous vaccines are generally so much superior to those obtained from stock emulsions that the conclusion is almost unavoidable. The almost uniformly mild course of those diseases which result from infection with *S. viridans* will suggest the prognostic value in the determination of the particular strain of the streptococcus which may be present in any given infection.

TOTAL HYSTERECTOMY IN TUBERCULOUS PREGNANT WOMEN.

It is generally admitted that if a tuberculous pregnant woman becomes rapidly worse in the early months of pregnancy, the latter should be terminated. The usual method is the artificial induction of abortion, but after the second month or thereabout the unfavorable result of the often copious and protracted hemorrhage must be borne in mind; and despite the care enjoined upon the husband in reference to the prevention of a further pregnancy such a contingency is very likely to happen. Hoehne at a recent meeting of the Medical Society of Kiel (*Münchener medizinische Wochenschrift*, October 24) commended the practice under these circumstances of total vaginal hysterectomy, including ablation of the adnexa. The idea was first carried out by Bumm upon a series of women now aggregating twenty-six. The author has thus far operated three times, but in one case he performed a supravaginal abdominal hysterectomy, leaving the adnexa intact. Hemorrhage was less than in the average abortion. Further, as general narcosis is not always justifiable in pulmonary tuberculosis, the author preferred lumbar anesthesia. Again, in these cases removal of the ovaries so far from being harmful was believed to exert a favorable influence in turberculosis. In any case, the latter disease showed quite a notable improvement as the joint result of interrupted gestation and castration.

Eck's Fistula and the Liver.

In theory an Eck's fistula in the dog furnishes a satisfactory opportunity for studying the hepatic functions in health and disease. In practice, however, the technique is often defective. Not only have many dogs died from the intervention, but certain accidents may prevent experimentation. Among these are pancreatic fat necrosis. The operative mortality, however, has now been reduced to about ten per cent. Unfavorable anatomical conditions may interfere with the proper establishment of a fistula. Fischler, at a session of the Naturhistorisch-Medizinischer Verein zu Heidelberg (*Münchener medizinische Wochenschrift*, December 5) now immunizes his dogs to trypsin before the operation, in order to prevent necrosis of the pancreas. He has studied especially protein metabolism and the so-called meat poisoning which invariably occurs promptly in emaciated dogs, but only after a considerable interval in fat animals. This intoxication is manifested by depression, anaurosis, ataxia, catalepsy, and stupor. If the liver is anatomically intact there are no phenomena of excitement, but the latter supervene if a degenerate state is present. The intoxication seems to be due to an alkalosis from the alkaline cleavage products of the meat. This would make it appear that a function of the liver is the neutralization by acids of these toxic alkaline products.

News of the Week.

Beriberi Suspects in Philadelphia.—Four East Indian sailors who arrived in Philadelphia on the British steamship *Karema* are held in quarantine at Marcus Hook suspected of having beriberi.

Meningitis in Texas and Oklahoma.—A dispatch from Dallas, Tex., says that the reports in regard to the prevalence of meningitis in North and East Texas have been very much exaggerated. There have not been more than 500 authenticated cases in the State; of this number 100 have been officially reported in Dallas, about 100 in Fort Worth, and 97 in Waco. The other cases are scattered over the State. A panic not justified by the situation has prevailed and the opinion is expressed that normal conditions will be reestablished in a few weeks. Many physicians from cities and towns in the Southwest have visited the hospitals in Dallas where they are instructed in means employed to combat the disease. There have been some cases of the disease in the extreme southern portion of Oklahoma, and Shreveport, La., has put into effect a rigid quarantine against all points in Texas where meningitis is known to be prevalent. All railroads have been ordered to discontinue selling tickets from such places to Shreveport.

Pellagra in Tennessee.—Dr. Olin West, who has been making an investigation under direction of the State Board of Health of Tennessee, has reported that he has found hookworm in ninety-five of the ninety-six counties of that State.

Epidemic of Measles.—More than 1,500 cases of measles have been reported in the city of Wilkesbarre, Pa.

The War on Bubonic Plague.—Since the epidemic of bubonic plague in San Francisco, in 1908, the Federal Government has expended more than $1,000,000 in combating it. At first efforts were made to exterminate rats, but, later, attention was turned to squirrels which have acquired fleas from rats, and among the myriads killed 10,000 have been found to be infected with the bubonic plague.

Anti-Mosquito War in Hawaii.—The Health Department of the Territory of Hawaii is conducting a vigorous crusade against mosquitos in Honolulu. The Federal Government has detailed Dr. G. W. McCoy of the Public Health and Marine-Hospital Service to serve as Sanitary Adviser to the Hawaiian Government and to have charge of the mosquito campaign.

The Death Rate for Chicago for 1911.—The death rate for Chicago for 1911 was 14.55 per 1,000, the total number of deaths being 32,672. The number of deaths from preventable disease was 1,600 less than for 1910. Pneumonia was responsible for the largest number of deaths, 4,929, and tuberculosis ranked next with 3,726. The death rate from typhoid fever was 93 per cent. lower than it was twenty years ago.

The Boston Death Rate.—The officials of Boston's health department state that the death rate of that city as given by the United States Census Bureau for the year 1911 was incorrect and that those of the Health Department are right. The actual death rate for the year was 17.1, while the figures given out at Washington were 18.5 per 1,000 inhabitants.

Many Lives Lost by Fire in 1911.—There were 497 lives lost by fire in Greater New York in 1911 as against 329 for 1910. This great increase was partially accounted for by the 147 lost in the Triangle Shirtwaist Factory disaster. This catastrophe led to the organization of the Committee of Safety, which, in cooperation with the Legislature and representatives of the city government, created the Bureau of Fire Prevention, which is doing considerable work in spite of an inadequate appropriation.

New York City Needs More Hospitals.—The report of the State Board of Charities, made public on January 12, shows that the hospitals of New York are greatly overcrowded. During the year ended September 30, 1910, the public hospitals cared for 88,085 patients and gave 1,669,766 days' treatment. The report states that the greatest amount of congestion was found in the Metropolitan Hospital, the Kings County Hospital, the City Hospital, the Cumberland Street Hospital, and Bellevue Hospital. In the latter alone there were more than 800 beds in excess of the normal capacity, and at times additional cots and mattresses were placed on the floor between the beds to accommodate the large number of patients. The number of mattresses thus used had aggregated as high as 480 in a single night. The need for hospital buildings that will accommodate 1,200 patients is imperative and provision should be made for a much larger number if the hospital facilities are to keep pace with the growth of the city.

Charitable Gifts.—A costume ball given at Sherry's on January 11 netted $5,000 for the Lying-in Hospital of New York City. In the will of Moritz H. Rosenstein there are bequests of $1,000 each to the Montefiore Home and Mount Sinai Hospital, and of $500 each to the Lebanon Hospital and the Hebrew Benevolent Society. Richard T. Crane of Chicago has left $2,135,000 to be devoted to charitable works; $25,000 will go to the Visiting Nurse Association and $10,000 to the Lake Geneva Fresh Air Home. Mrs. Mayer Lehman has given $100,000 to Mt. Sinai Hospital, the income of which is to be used in preventive work. It is not yet decided just what course this work of prevention will take, the planning of which

will be left mainly to the medical staff, but it will doubtless be done mainly in the homes of the poor and will include an extension of the present work of the visiting nurses.

The Western Reserve University, located at Cleveland, O., has completed its fund of $1,000,000 which is to be used as a permanent endowment for its Medical Department. About a year ago John D. Rockefeller agreed to give $250,000 of this amount contingent upon the institution raising the remainder. Mr. H. M. Hanna then gave another $250,000, and this was followed by two gifts of $100,000 each, one of $50,000, three of $30,000, two of $25,000 each and several smaller amounts which completed the fund. The Western Reserve Medical Department represents the absorption and consolidation of five medical institutions which have existed from time to time in Cleveland, the oldest dating back to 1835. This institution was one of the first to require college preparation as one of the conditions of entrance.

To Investigate Chicago Medical Colleges.—The Chicago Medical Society has appointed a committee to investigate seven medical colleges recognized by the State Board of Health. One of the objects of the investigation, in addition to the betterment of facilities, is to secure accurate statistics so that the findings of philanthropic investigators may be disputed or upheld in a decisive manner.

The Hat-Pin Law in Zurich.—Owing to the many accidents in street cars and trains which have resulted from projecting hatpins a law was put into effect on January 1 prohibiting the wearing of unprotected hatpins. In a single day gendarmes arrested 110 women of all classes who were fined 5 francs each.

A New Hospital for Stamford, Conn.—Work has been begun on a new hospital for Stamford which it is estimated will cost over $319,000, all of which amount is in hand except about $30,000. It is expected that the plant will be ready for occupancy in eleven months.

New Hospital for Nelson, B. C.—A $70,000 hospital building is to be erected in Nelson toward which the people have voted to authorize a civic grant of $15,000.

Clinton Hospital Near Completion.—A new maternity hospital has been erected in connection with the general hospital of Clinton, Mass., which will be ready for occupancy about March 1.

New Post-Graduate Hospital Buildings Opened.—The new buildings and laboratories of the Post-Graduate Medical School and Hospital were opened for inspection on January 11. The new building adjoins the old one and contains 480 rooms, or 130 more than the old building, and was erected at a cost of $1,500,000. It is claimed that there is nothing for the work of post-graduate instruction that has been omitted from the equipment of this institution. In the evening a dinner in commemoration of the opening of this building was given at Delmonico's where more than 200 members of the staff of the hospital and their guests were present. Dr. George M. Miller presided. The speakers were Dr. Samuel W. Lambert, Dean of the College of Physicians and Surgeons of Columbia University; Brigadier-General G. H. Torney, Surgeon-General of the Army; James M. Beck, Dr. Abraham Jacobi, and Augustus E. Thomas.

The American Hospital Association will hold its Fourteenth Annual Conference in Detroit, Mich., on September 24, 25, 26, and 27, 1912. Any information regarding this association, as well as application forms for membership, may be had by addressing the secretary, Dr. J. N. E. Brown, Toronto, Canada.

The Harvey Society Lecture on January 20 will be delivered by Prof. Henry Fairfield Osborn; the subject will be: "Unit Characters in Heredity as They Appear to a Paleontologist."

Public Health Lectures.—The series of lectures which form a part of the New York work of the American Medical Association Public Health Education Committee, which are given under the joint auspices of the Public Health Education Committee of the Medical Society of the County of New York and the Hygiene Committee of the New York City Federation of Woman's Clubs, will be given at the New York Academy of Medicine on alternate Wednesday evenings and Thursday afternoons from January 10 to March 28, 1912.

The Medical Association of the Greater City of New York held its annual election of officers on January 15. The following were elected: *President*, Dr. Reynold Webb Wilcox; *Vice-President*, Dr. Ransford E. Van Gieson; *Corresponding Secretary*, Dr. Frank C. Raynor; *Treasurer*, Dr. A. Ernest Gallant; *Chairman for Borough of the Bronx*, Dr. Nathan B. Van Etten; *Chairman for Borough of Brooklyn*, Dr. Robert E. Coughlin; *Chairman for Borough of Queens*, Dr. L. Howard Moss.

Report of the Finance Committee of the New York Academy of Medicine.—Dr. L. Emmett Holt, chairman of this committee, in his annual report, said that the committee is of the opinion that the first step toward the end in view, namely, the enlargement of the academy, is to pay for the real estate which was purchased a little over one year ago. This will require just double the amount thus far subscribed. Up to the present $110,000 has been subscribed by 329 members, or about one-quarter of the membership. With the real estate free from all indebtedness the academy would then be in a strong position to ask the outside public for a new building. The committee urgently asks the hearty cooperation of those who have already given in securing subscriptions from others, and of those who as yet have not subscribed to do their part as generously as others have done.

A Tour for Foreign Physicians.—In connection with the International Hygiene Congress, which will meet in Washington in September, a six weeks' tour has been arranged for visiting physicians which will embrace visits to New York, Philadelphia, Atlantic City, Baltimore, Washington, Chicago, Montreal, and Albany. It is announced that the cost of this tour will be from $425 to $625 from Europe and return.

Physicians in the United States Number 130,000.—According to the last census there are 130,000 physicians in the United States; this includes doctors of every description, as well as osteopaths, psychopaths, hydropaths, etc. There is one doctor to every 650 of the population and the average income of a physician is said to be $1,200 per annum.

Vital Statistics Legislation.—In a report of this subject it is pointed out that in only 24 of our States do we know how many human lives are lost each year; in 25 States no books are kept. In only 9 States are any birth records kept, and in most of these this has been done but a few years. In the census report for 1910 the fact appears that our

death ratio is based on returns from only 58.3 per cent. of the entire population. In Alabama, Florida, Georgia, Kentucky, Louisiana, South Carolina, Tennessee, Texas, and Virginia an effort has been made to register deaths in the larger cities, but none has a general registration of deaths or recording of births. Proper legislation for securing vital statistics is urged in these States. Aside from the value of vital statistics from the point of view of public health, birth records have an important legal significance, as attested by the following instance: George A. Wagner of Manchester, N. H., has been elected Probate Judge of Hillsboro County, but cannot take office because no record of his birth can be found.

British Medical Association.—The eightieth annual meeting of this Association will be held at Liverpool, July 23-26, 1912, under the presidency of Prof. Robert Saundbey, Sir James Barr being the president elect. The address in medicine will be delivered by Dr. George Alexander Gibson of Edinburgh; the address in surgery by Mr. Frank Thomas Paul of Liverpool.

The Seventeenth International Medical Congress will be held in London, August 6-12, 1913, under the presidency of Sir Thomas Barlow. The usual rules have been adopted. The official languages will be English, French, and German, though Italian will be allowed in the reading and discussion of papers. The subscription will be $5.00 for members and $2.50 for the wives and daughters of members accompanying them. Members will receive the volume of the transactions recording the proceedings at the general sessions and also that of the section in which they have been enrolled. The program of the Congress and of its various sections will be published not later that September 30, 1912, and will be sent to all those who shall have inscribed themselves as members before that date. Information concerning the reductions in fares granted by railway and steamship companies, hotel and boarding-house accommodations, excursions and other entertainments, etc., will be published before April 30, 1913.

Dr. Albert Warren Ferris of New York, who resigned from the post of president of the State Commission in Lunacy to resume the general practice of internal and nervous diseases, has been appointed resident physician of The Glen Springs, Watkins, N. Y., and will take up the duties of his new position in February.

The North Central Branch of the American Urological Association will be held in St. Louis on February 5, 6, and 7. The headquarters of the meeting will be at the Jefferson Hotel, Twelfth and Locust streets. Hotel reservations may be made through Dr. Bransford Lewis, 1050 Century Building, St. Louis.

The Ninth International Red Cross Conference will be held in Washington, D. C., from May 7 to 17, 1912. In connection with the meeting there will be an exhibition, divided into two parts, the Marie Feodorovna and the General, the former of which offers prizes aggregating approximately $9,000 and the latter approximately $3,000. Information regarding this prize competition may be obtained from the Chairman of the Exhibition Committee, American Red Cross, Washington, D. C.

A Hospital for Animals.—The New York League for Animals plans to build a hospital somewhere on the East Side of the city, the object of which shall be to care for sick animals that work or those that are pets until they are cured. This idea is new in this country, but has been put into practice in both London and Paris. The league already has a dispensary in Lafayette street, where more than 500 cases a month are seen to. They plan to expend $225,000 on the hospital, and $50,000 has already been contributed, of which Mrs. Russell Sage has given $10,000, Mrs. Alfred G. Vanderbilt $10,000, and a like amount by an anonymous donor.

A Memorial for Dr. William Price Pryor.—Dr. J. B. Rolster of Oklahoma City, Okla., has given the sum of $500 toward the erection of a memorial tablet to the memory of the late Professor William Rice Pryor to be placed in the new building of the New York Polyclinic Medical School and Hospital.

A Memorial Hospital.—The Hospital Corporation of Springfield, Mass., announces that $30,000 of the $50,000 required for the proposed memorial to Dr. Frederick W. Chapin, formerly vice-president of the institution, has been pledged. This memorial will take the form of an addition to the Springfield Hospital, which is badly in need of larger accommodations.

Hospital Gifts Fall Off.—The annual collection of the Saturday and Sunday Association, which is taken up in one hundred churches of New York, amounted this year to only one-half as much as usual, only $15,000 having been contributed.

Dental Surgeons Wanted in the Army.—The Surgeon-General of the Army announces that there will be examinations for the appointment of Acting Dental Surgeons on April 1, 1912. Application blanks and full information concerning these examinations can be procured by addressing the Surgeon-General, U. S. Army, Washington, D. C.

Dr. W. W. Keen of Philadelphia has been re-elected president of the American Philosophical Society.

Dr. Walter S. Cornell has been appointed Director of Medical Inspection of Schools of the City of Philadelphia. He will be in charge of a staff of fifty-five physicians who will constitute, under the new school code, the medical examiners for the public schools. He will have under his charge fifty-five nurses, who will administer to the children in the schools, visit their homes, and see that the physicians' orders are carried out.

Physicians' Motor Club of Philadelphia.—At the annual meeting, held January 9, Dr. S. Leon Gans was elected *President;* Dr. L. Webster Fox, *First Vice-President;* Dr. John I. Robrecht, *Second Vice-President;* Dr. Charles A. E. Codman, *Third Vice-President;* Dr. J. Gurney Taylor, *Secretary,* and Dr. Lewis H. Adler, Jr., *Treasurer.*

Dr. A. S. Begg of the Harvard Medical School has been appointed to the Chair of Histology and Embryology in the Medical Department of Drake University, Des Moines, Iowa.

Dr. Harry T. Inge of Mobile, Ala., has been appointed Chief Surgeon of the Mobile and Ohio Railroad Company, to succeed Dr. Rhett Goode, deceased.

The Manhattan Medical Society will meet at Reisenweber's Café on Friday evening, January 26. The papers to be presented will deal with the ethical and financial relations of the physician.

Obituary Notes.—Col. Egon A. Koeper died at his home in Washington, D. C., January 11, at the age of 76. He was deputy surgeon-general for the army some time ago and retired from practice a number of years ago. He was born in Prussia, where he received his early military training.

Dr. Frank Baldwin of Brooklyn, N. Y., a

graduate of the New York University Medical College in 1877, died from pneumonia at his home on January 13 at the age of 57 years. He was a member of the Kings County Medical Society and the Brooklyn Gynecological Society as well as of many others.

Dr. F. J. Yager of Campbellsburgh, Ky., died at his home, January 10, at the age of 90. He had practised medicine for over seventy years.

Dr. Virginia F. Bryant of Nahant, Mass., a graduate of Boston University School of Medicine, Boston, in 1884, died at her home, January 4, at the age of 54 years.

Dr. Charles W. Taylor of Lowell, Mass., a graduate of the Medical School of Harvard University, Boston, in 1884, died at his home, January 4, at the age of 52 years.

Dr. James S. McLaughlin of Westfield, Mass., a graduate of Dartmouth Medical School, Hanover, in 1893, died at his home January 2. He was 46 years old.

Dr. Joseph R. Pollock of Fort Worth, Tex., a graduate of Hahnemann Medical College and Hospital, Philadelphia, in 1871, died at his home, December 27, at the age of 66 years.

Dr. John D. Bedford of Honeygrove, Tex., a graduate of Missouri Medical College, St. Louis, in 1883, died in Dallas, Tex., December 31, at the age of 54 years.

Dr. W. T. Whiting of Lafayette, Col., an assistant to Dr. Victor W. Porter, was killed when his automobile collided with an interurban car. He was 25 years old.

Dr. John W. Quillian of Gainesville, Ga., a graduate of Atlanta Medical College in 1873, died at his home, January 5, at the age of 65 years.

Dr. Frank E. Bundy of Boston, Mass., a graduate of the Medical School of Harvard University, Boston, in 1862, died January 6 at the age of 73 years. He had studied under Dr. Oliver Wendell Holmes and was a member of the Massachusetts Medical Society.

Dr. William P. Kistler of Allentown, Pa., a graduate of Bellevue Hospital Medical College in 1867, died January 8 at the age of 67 years.

Dr. J. Cameron Struthers of Hazelton, Pa., a graduate of the Medico-Chirurgical College of Philadelphia, died at his home, January 8, at the age of 32 years.

Dr. James A. Hopkins of Milton, Del., a graduate of Jefferson Medical College, Philadelphia, in 1858, died January 8 at the age of 78 years.

Dr. Robert Sanders died at Palmerton, Pa., on January 5, at the age of 24 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1910. He was interne at the Palmerton Hospital.

Dr. Morris F. Cawley died suddenly at Allentown, Pa., on January 6, at the age of 55 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1888. He was Surgeon-Major of the Fourth Regiment, N. G. P.

Dr. Oscar Howe, of Fisherville, Mass., the oldest man in South Grafton and at the time of his retirement four years ago the oldest practising dentist in Massachusetts, died on December 29, at the age of 81 years.

Dr. James S. McLaughlin of Westfield, Mass., a graduate of Dartmouth Medical School, Hanover, in 1893, died at his home January 2, at the age of 46 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE INSURANCE ACT, MEETINGS AND PROTESTS—THE UPRIGHT POSITION DURING ANESTHESIA—THE VARIETIES OF CHLOROFORM—LONG AS A PIONEER—ARTHRITIC DISEASES.

London, December 29, 1911.

The war against the Insurance Act is still being waged with vigor. The requisition for a general meeting of the B. M. A., signed by above 500 members, was presented on Wednesday and by the by-laws this must be convened within twenty-one days—therefore it must be held next month. But the articles of association provide that resolutions passed at any such meeting have no effect on the Council. If they dislike it they can obstruct any action upon it for half a year, and moreover the members of the Council can decline to resign, thereby retaining the administration in their own control, however hostile may be their constituents, just as the present government is holding onto office although it is universally admitted that the English electors have no confidence in it. When the Association was reorganized there was much talk of securing representation on the Council, but, excellent as the rules may look at first glance on paper, some of the older members predicted that they would work in such a way as to preserve the powers of the "inner clique," and that is what has happened. It is quite possible for the Council, while preserving the letter of the by-laws, to defeat their intention and defy the members. How far the dignity of the majority of the Council, now that the position is becoming plain, will permit them to hold onto office remains to be seen. There is certainly a demand for their resignation from a large proportion, probably a majority, of their constituents. It is stated and generally believed that Mr. Lloyd George admitted he could not carry the six points through the House of Commons, and for this reason the socialistic element on the Council sacrificed the profession to the political exigencies of the Chancellor. This is regarded as admitting of no excuse and is to a great extent accountable for the refusal to hear Sir V. Horsley. But the general apathy of the profession is at the bottom of the mischief—neglecting to elect representatives who understand the questions that concern practitioners and will insist on their rights.

The great London meeting which I described last week has been followed by many others in various parts of the country, and they mostly endorse the resolutions of that mass meeting.

In Manchester the projected formation of a "National Medical Union" is almost complete and influential members of the profession from many districts are daily being added to the committee. This union is not opposed to the B. M. A., but rather intended to compel the older body to do its duty in the present crisis.

In Scotland the two colleges and the faculty have held meetings and decided to issue a manifesto urging united action to get their demands granted by the Insurance Commissioners, failing which they will advise all practitioners in Scotland to refuse to work under the act. A voice of dissent has been raised in Edinburgh, where Dr. C. F. Knight defends the act and is trying to organize a society to carry it out. It does not seem likely that his opposition will accomplish much, but it

illustrates the statement of elderly practitioners that the profession has "never been unanimous and never will be."

The referendum issued by the *Practitioner*, asking a pledge not to serve under the act, has been responded to by more than half the number of 23,000 stipulated for as necessary to make the promise binding. Sir James Barr, who is president-elect of the B. V. M. A., telegraphed his reply to the *Practitioner*, wishing it success and adding: "Insurance Act must not be allowed to disgrace the statute book."

Anesthesia has been more than usually prominent in our conversation of late, perhaps because it is proposed by some to adopt the upright position of patient being subjected to chloroform. Dr. J. H. Chaldecott, anesthetist to St. Mary's Hospital, brought this proposal before the Harveian Society on December 7 in a paper in which he stated that he had given chloroform in the upright position to 1,400 persons without any fatality and, in fact, without the occurrence of symptoms of danger. Old traditions die hard, and the traditional recumbent position is so general that at present few have ventured to try another, and it must be admitted that there was good reason for adopting the posture that has become so universally considered the safest. Dr. Chaldecott is, however, one of the few who have tried the upright position and he has been so satisfied with it that for the past six years he has continued to do so as often as possible. For some operations I must agree with him that it is much more convenient for the operator, and as he has found it more comfortable for the patient, and in such cases safer, we may expect it to be more frequently adopted. In nasal and nasopharyngeal operations it must be most convenient, and some useful hints were given to insure success; thus the patient must be properly prepared so as to avoid unnecessarily deep anesthesia and so prevent vomiting. A high-back chair must be used to keep the patient bolt upright. This is most important, as an easy chair lets the patient slip down into "a huddled up position," and any chair with arms lets them get in the way. The feet should be supported on a high stool or another chair to prevent the patient from fixing them on the floor and pushing backwards. Stress was laid on the method of holding the patient's head; the anesthetist, standing behind, should support it on his chest during induction. When ready for operation he should pass his left arm around the neck to control it, holding the inhaler tube with the fingers and feeling at the same time any swallowing movements or variation of pulsation in the neck vessels. The right hand works the bellows and sponges out the mouth if needful. A dental prop should always be used for nasal cases, as the tendency to asphyxial symptoms requires the mouth to be kept slightly open throughout. To prevent struggling, gas or ether may be used at first or ether and ethyl chloride. The safety of the patient is always the first consideration, and as to this Dr. Chaldecott concludes that the upright position is the safer, and for nose and throat operations many will endorse his views. In his 1,400 cases the breathing was more quiet, syncope did not occur, nor any other alarming symptom; mucus did not pass into the larynx and tongue forceps were seldom required. A sponge in the nasopharynx was recommended, though some surgeons object on account of blood turned into the anterior curves obscuring the view, but it is less inconvenient than frequent sponging. Vomiting was less common than in the traditional posture.

In the Section on Anesthetics (R. S. M.) a letter from the editor of the *British Pharmacopœia* asked for an opinion on the propriety of including chloroform derived from methyl alcohol. The general opinion was decidedly in favor of its inclusion, although one member thought the ethyl product less dangerous. Others were convinced there was no difference and that acetone chloroform was also equally good. The point most important was that whichever was employed must be pure. One member remarked that rather more acetone chloroform was required than of ethyl or methyl, and said experiments on animals bore out his view. The president thought that, as in each case the end produced was the same, it was not material from what source it was obtained. A question as to whether a committee should consider the question was negatived and the meeting decided to reply that methly chloroform should be included in the B. P., and further recommended the inclusion of acetone chloroform.

Dr. Dudley Buxton read a paper on the pioneer of ether anesthesia—Crawford Long, a man who had a horror of advertisement or of premature exploitation of results of research. Long observed that painful knocks were not felt under ether and used it, therefore, in 1842 instead of gas, and his work was well known in the State of Georgia. When Morton sought recognition for his nostrum, lethion, which was only ether, Long was persuaded to publish his cases—earlier by 4½ years. This proved his claim to be the first to try ether for producing anesthesia. After an account of Long's career Dr. Buxton dilated on the state of medical opinion at the time concerning mesmerism and other attempts to secure insensibility to pain during surgical operations. He traced the methods tried from 1841 to 1911 and compared their results, concluding with an appeal to anesthetists to supplement their practical skill by actual scientific research.

The nomenclature of chronic arthritic diseases was the subject of a paper by Dr. Burt at the Manchester Medical Society. He thought their great chronicity was an important cause of their bewildering classification, as secondary changes took place before postmortem examinations could be made, so that the pathological appearances were largely due to wear and tear. Mr. Lane had shown that excessive use of a healthy joint would induce osteophytes, and destruction of cartilage. Slides were shown to illustrate such formations in the cobbler's thumb, the miner's right hip, and the left knee in cases of right hemiplegia. Bony formations were most frequently met with in those diseases in which movements were encouraged, *e. g.*, gout, senile arthritis. But in cases of great damage to ligaments or bone giving much pain on movement, osteophytes were rare, though if such cases improved enough to permit movements, wear and tear would come into operation and bony additions would result.

Anatomical Alterations of the Sweat Glands in Disease.—Veit denies that these changes occur even in nephritis. The former positive findings are attributed to post-mortem artefacts of autolytic and bacterial origin.—*Deutsches Archiv für klinische Medizin.*

OUR LETTER FROM PARIS.

TREATMENT OF REBELLIOUS COLITIS—TREATMENT OF DEEP EXTRAPULMONARY TUBERCULOUS LESIONS BY RADIUM—TREATMENT OF SYPHILIS WITH 606—HYDATID CYSTS OF THE KIDNEY—DIAGNOSIS AND TREATMENT OF CHRONIC POSTERIOR URETHRITIS—NECROLOGY.

PARIS, December 15, 1911

THE surgical treatment of rebellious colitis was the subject of a long discussion which has just been ended. According to Jacob in France colitis was considered exclusively a medical disease, and only exceptionally was the surgeon called upon to treat it. The surgical treatment of rebellious colitis may be carried out by three operations: appendicostomy, cecostomy, and ileosigmoidostomy. The first two only may be used in chronic dysenteric colitis. Appendicostomy consists in the approximation of the appendical cavity to the skin of the abdomen, with the object of making lavage of the large intestine through the appendicular canal. This is a simple, benign operation; it causes no infirmity, and makes a simple, continent fistula, allowing to pass out neither fecal matter nor the wash-water, and from this point of view it is superior to cecostomy, which makes a true artificial anus which is especially disagreeable to the patient. Cecostomy should be utilized in grave cases in which it is necessary to place the large intestine at entire rest; it is useful only in those cases in which it is the only hope of recovery for the patient. Sieur thinks that in the presence of a grave colitis with fever and ulcerations in the rectum and anus we should rather undertake cecostomy. Moty thinks that the indication for appendicostomy is present in severe dysenteries as plainly as for the removal of the appendix in appendicitis. He advises operation not only in chronic cases, but also in acute or subacute ones which do not yield rapidly to medical treatment. The treatment of deep extrapulmonary tuberculous lesions by the introduction of tubes containing radium into the tuberculous tissues was taken up by Dominici and Cheron, who have thus obtained most interesting results. The authors conclude that radium therapy is not only superior to other methods of treatment of tuberculous lesions, but that it is certain and efficient in osseous and glandular tuberculosis: they think that we should combine the action of this therapeutic measure with that of surgery and various other physical agents such as x-rays, hot air, diathermia, etc.

The treatment of syphilis with 606 was presented by Hallopeau, who described a case of death after injections of 606 in a relatively healthy subject. This was a man thirty-five years of age who had contracted syphilis seven years before, in 1902. The patient had a first injection intravenously of 30 centigrams, which was well borne; on the sixth day he was given a second injection of 40 centigrams, which was followed by severe symptoms and death four days afterward. Hallopeau thinks that 606 is a dangerous remedy which has several times caused death of relatively healthy subjects. Gaucher knows other similar cases, and holds not only that 606 does not cure syphilis but that it is a dangerous product, being a violent nerve poison; all the patients who have died after injections of 606 have died with epileptiform attacks. In a case of death in which the viscera were analyzed death seems to have occurred through a subacute arsenical intoxication causing uremia and kidney degeneration. Balzer and Pierre Marie think that 606 is not as dangerous a remedy as has been alleged; if it is methodically and prudently used it renders great service.

Paul Bar gave the results that he obtained in pregnant syphilitic women treated with 606. He has noted that this remedy has a rapid action on mucous patches; in intravenous injections this drug has produced no severe immediate symptoms. As an untoward effect he has observed in a pregnant woman a severe albuminuria. In the new born at term, if syphilitic, 606 is useful in causing the disappearance of symptoms. Emery, who has studied especially the action of 606, has published an article on this subject in *La Clinique* for November, 1911, in which he states that in the large number of cases the symptoms would have been prevented by a prudent employment of the medicine and a dosage more proportional to the apparent resistance and the organic integrity of the patients. In almost all the cases in which fatal results have been reported the dose of 40 centigrams had been exceeded. Emery has seen no bad result in any of the 1,400 patients whom he has treated, and he thinks that this immunity has been due to the prudence with which he limited the doses injected. The maximum dose should be 30 centigrams, but it should be no greater than 10 centigrams in debilitated, cardiac, albuminuric, and nervous patients. With this remedy he has obtained in all periods of the disease the most complete and permanent clinical results.

The French Urological Association held its fifteenth session at Paris from the 5th to the 7th of October, Raffin of Lyons being president. The question of the day was non-hydatid cysts of the kidney. Letulle and Brin of Angers presented papers on this subject. True cysts of the kidney are of two kinds: (1) The polycystic kidney, which belongs to the category of embryonic malformations; (2) serous cysts of the kidney, which may be observed in healthy or pathological kidneys. In the healthy kidney the serous cyst seems to be of congenital origin; in diseased kidneys the cysts result necessarily from retention, and appear to date back to the earliest development of the kidneys. Large serous cysts should be treated by resection of the pocket, like hematic cysts. The polycystic kidney should not be operated on: we should never operate except when they present complications. Pousson, Lugueux, and Carlier took part in the discussion of this subject.

George Luys presented three excellent projections of pictures taken from nature, representing the principal lesions of the posterior urethra observed in the course of chronic posterior urethritis. It is impossible, he said, to diagnose and treat a posterior urethritis unless we make use of direct control by means of a urethroscope. Neither the examination of the urine in four glasses nor the exploration by means of an olive bougie, nor even rectal touch of the prostate will give evidence of the gross lesions of the prostatic urethra. The symptoms of which the patients complain are general and badly defined: they generally consist simply of impotence, ejaculation troubles, and pains irradiating into the thighs or lumbar region, but none of these symptoms is characteristic. The only method of making a perfect diagnosis is to practice urethroscopy by the simple straight tube introduced into the posterior urethra; the treatment

should consist first of a slow and methodical dilatation of the posterior urethra, and then of applications made directly by sight, and consisting of the actual cauterization, or application of tincture of iodine, or of a solution of silver nitrate.

Henri Monod, Director of Public Charities and Hygiene to the Minister of the Interior, Commander of the Legion of Honor, has just died at the age of 68 years. He organized in France a sanitary defense against great epidemics. It was he to whom we owe the systematic organization, the rational and efficient defense against pestilential maladies of our country; the "International Office of Hygiene" was his last creation. It was he who took the most active part in the enactment of laws for the practice of medicine and the protection of the public health. He was very active also in bringing about a law for the obligatory assistance of old and infirm persons; he thought that society should assist all those whom age or infirmities render incapable of self-support. He believed that all unfortunates not manifestly responsible for their own misery should be assisted. But above all Henri Monod was a zealous worker for social preservation, especially with reference to tuberculosis.

CANADIAN PUBLIC HEALTH ASSOCIATION.

(From Our Special Correspondent)

THE section devoted to the consideration of social questions had its meeting on Thursday morning, December 14. This was essentially a woman's meeting, the greater number of the papers read being by women and the presiding officer being Dr. Grace Ritchie England. Dr. George Adami, Professor of Pathology, McGill University, read the first paper, his subject being the value of exhibitions as agents in the public health campaign. The speaker has a high opinion of the value of exhibitions from the sanitary educative standpoint and thought that the daily press was becoming one of the most effective agents in making people aware of the defects in conditions relating to public health. A very excellent paper was read by Miss Ethel Hurlbatt, Principal of the Royal Victoria College, Montreal. The speaker said that Canada was beginning to realize that the health and well-being of the individual involved that of the community, and the latter was coming to recognize its duty in enforcing proper precautions for the care of individual lives. Miss Hurlbatt suggested that there was need of women sanitary inspectors in factories where women were employed as well as in many homes.

An extremely interesting paper was contributed by Dr. A. D. Blackader, Professor of Pharmacology and Therapeutics, McGill University. The subject discussed was that much-debated matter, the more important causes of infantile mortality in large cities and the influence exerted by milk depots. Attention was drawn to the fact that in England fourteen out of every one hundred born die during the first year. The rate is higher in many European cities. In the Province of Quebec the number is eighteen and in Ontario fifteen. In New York it has been brought down from twenty-six to eighteen because of greater attention to sanitation and the milk supply. In Montreal the death rate from all causes looks small when compared with the tremendous mortality of infants. The argument that those who are not very strong die, and that thereby the world may be better off in the end, does not hold good. Some of the most brilliant men of the ages have been very delicate as infants. Sir Isaac Newton, for example, was brought safely through the period of infancy only by great care and attention.

A feature of the meeting was a symposium on town planning and housing. This is a matter of great moment to Canada, as, in the East in particular, overcrowded slums in cities are forcing themselves upon the notice of the public. Dr. Helen MacMurchy, Toronto, read a lengthy extract from a report made by Sidney and Beatrice Webb, who last year made a trip through Canada in order to observe social and economic conditions. Their conclusions were as follows: "To put it shortly, the Canadian city is still essentially uncivilized, it is neither properly paved nor drained, nor supplied with water fit to drink, nor equipped with any adequate public health organization. This is particularly true of the cities of Quebec and Ontario, proud as they are of their civilization. The newer cities of the West have gone in much more for collectivist organization of the means of healthy city life. But after ages will wonder at the stupidity of a government and a people which take so much trouble to bring in immigrants from every corner of Europe, even the Ruthenians and Armenians, and for sheer lack of public thought let its own Canadian babies die in quite unnecessary holocausts, and for sheer lack of civic organization allow even the laborers it has brought over to be decimated by enteric fever due to a contaminated water supply." Some of the papers read were even more harsh in their criticisms. Dr. Charles A. Hodgetts, Ottawa, dealing with the question of town planning and housing, said in part that one must acknowledge that Canadians were behind the times and had made and continue to make serious mistakes in the laying out of cities and towns, and in not planning for their development. Acknowledging this fact, it was the duty of Canadian citizens to learn by the mistakes of the older countries of Europe. The lumber town of forty years ago was still the lumber town; overgrown, it had not risen to the realization of its importance or to the dignity of its position as the federal capital of a great and growing nation. Nor did the great seaport of Canada, its commercial capital, present any outstanding features to lead one to eulogize the foresight of its healthy and intelligent citizenship or the system adopted of converting a once fine family residence into an apartment house or a tenement house of the worst type. All the new and older cities, according to the speaker, were, from the town planning and housing standpoint, monstrosities. Dr. J. E. Laberge, Assistant Medical Officer of Health, Montreal, discussed town planning and civic authorities. He remarked that until recently this important matter had received little consideration from the public authorities, due to the ignorance of the public in matters of hygiene. "Have wide boulevards in the place to which you transfer the people from the crowded slums. Let these outside surroundings be places where the people can obtain air, light, good and abundant supply of water, and good housing. This work should not be left to outside enterprise, but should be taken up by the municipal authorities. To educate the citizens to see that their city becomes large, beautiful, healthful, sound, and prosperous." In a paper entitled "Housing Problems" Dr. Charles J. C. O. Hastings, Medical Officer of Health, Toronto, described the unsanitary conditions existing in the

slum districts of New York, Milwaukee, and Toronto. It was pointed out that Toronto had its slums as other cities, and it was of no use for people to try to disguise the fact, but the inhabitants must wake up, like the inhabitants of other cities, to the prevailing conditions, and not live in a "fool's paradise." He said that in Toronto there were 910 families living under distinctly unsanitary conditions, some only in one-room tenements or in cellars. Tenement houses the speaker declared to be nothing more nor less than mere packing houses, human packing houses, and he urged the necessity for securing transportation facilities to districts on the outskirts of cities, where people could be properly housed in individual homes in beautiful garden cities.

The last general session was given over to a discussion of biological sewage disposal. Dr. P. H. Bryce, Chief Medical Officer, Department of the Interior, Ottawa, gave the first address of this symposium on the physical and economic aspects of biological sewage disposal plants. He gave a history of the development of methods and knowledge of this subject, and dealt with the points embodied in his paper in an instructive manner. Mr. Willis Chapman, C.E., Toronto, referred to the progress in Canada in biological methods of sewage disposal during the past twenty years. Berlin, Ontario, was the first municipality to adopt sewage purification works, after several government institutions in Canada had made experiments with various methods. Many other places had adopted methods of different kinds, but the first septic tank was tried in 1901, though the septic tank boom is now beginning to subside. He made the prophecy that at the end of the decade now dawning every municipality in the Dominion of Canada would have sewage purification works.

Mr. T. Aird Murray, C.E., Toronto, spoke of the engineering problems involved in biological methods of sewage disposal. He exemplified this by a description of the sewage disposal works designed by himself at Lethbridge, with the view of securing the maximum removal of suspended solids, and said that the most that had been done was to secure an effluent that could easily and economically be rendered nonpathogenic. Dr. G. G. Nasmyth, Toronto, told of the chemical problems involved in methods of sewage disposal. He said that the oxidation processes practically involved the chemical process, in that organic matter acted on by oxygen became inorganic matter and humus. Bacteria in presence of air were essential for purification of sewage. In the opinion of the speaker the trickling filter system, from the point of view of economy and success, had come to stay, because it was in line with the methods of nature.

Dr. J. A. Amjot, Professor of Hygiene at Toronto University, read a paper embodying his views on the bacterial problems involved in biological methods of sewage disposal. He pointed out that it was only possible by bacteria to dispose of sewage properly. Two methods were ordinarily employed for this purpose, the anaerobic and the oxidation. The first method compelled the holding of sewage for about twenty days, although probably 50 per cent. of the bacterial action occurred during the first twenty-four hours. The oxidation method was more satisfactory by far, but even with it it was utterly impossible to secure any system in the results. The sludge tanks would reveal many different kinds of bacteria, even if they were treated alike. In them the oxidized matter was retained and treated for a day or two; little could be accomplished in a few minutes. The engineer must decide the exact way in which the system should be worked. It was decidedly not safe to depend upon slow sand filtration alone, and disinfection should also be employed.

The officers for 1911 were Dr. T. A. Starkey, Professor of Hygiene, McGill University, *President;* Major Lorne Drum, Permanent Army Medical Corps, Ottawa, *General Secretary;* Dr. G. D. Porter, Toronto, *Treasurer.* At a meeting of the Executive Council held on the afternoon of December 15 the new officers of the Association elected were: *President*, Dr. Charles A. Hodgetts, Ottawa. *Vice-Presidents*, Drs. M. M. Seymour, Regina; J. W. S. McCullough, Toronto; E. Bayard Fisher, Fredericton. *General Secretary*, Major Lorne Drum, Ottawa. *Treasurer*, Dr. G. D. Porter, Toronto. The next place of meeting will be Toronto.

THE CAUSATION OF UTERINE CANCER.

To the Editor of the Medical Record:

Sir:—In pursuance of the research which has for its object the determining whether or no the incipient stage of cancer of the uterus is coincident with maximum weight, strength, and health of the patient, a second series of cases has been collected in addition to those already published in Medical Record, May 20, 1911. Averaging up both series, which embrace collectively 53 uterine cancer cases and 26 controls (unfortunately no account can be taken of the additional 32 controls which failed to specify any definite time of maximum weight, but which report "Never gained in weight," "Have always been thin," "Indigestion for years," or somewhat similar conditions, which would preclude the probability of maximum weight in recent years), the following results are obtained:

Average age of 32 uterine cancer patients in Series 1, 49 years.

Average age of 21 uterine cancer patients in Series 2, 48 years.

Average age of 13 control cases in Series 1, 53 years.

Average age of 13 control cases in Series 2, 47 years.

(Average age of 32 omitted control cases, 48 years.)

Average maximum weight of 32 uterine cancer patients in Series 1, 3 years ago.

Average maximum weight of 21 uterine cancer patients in Series 2, 4 years ago.

Average maximum weight of 13 control cases in Series 1, 18 years ago.

Average maximum weight of 13 control cases in Series 2, 15 years ago.

Summing up the two series, we get:

Average age of 53 uterine cancer patients, 48 years 6 months.

Average age of 26 control cases, 50 years.

Average maximum weight of 53 uterine cancer patients, 3 years 6 months ago.

Average maximum weight of 26 control cases, 16 years 6 months ago.

Conclusion.—The maximum weight of uterine cancer patients is coincident with the incipient stage of the disease.

Relation of Chronic Appendicitis to Colitis. M. V. Tyrode
Rontgenology of the Enteron. H. W. Van Allen.
Memorials to Dr. Thomas Dwight; 1, J. Collins Warren; 2, J. B. Blake; 3, D. Cheever.
A Case of Cesarean Section for Placenta Previa. J. G. Hanson.

Relation of Chronic Appendicitis to Colitis.—M. W. Tyrode reports a series of cases illustrating the frequent coexistence and interrelation of colitis and appendicitis. The author does not discredit operations for chronic appendicitis, but merely pleads for more thorough attention to the colon before rushing chronic cases to operation. He also emphasizes the great necessity of after-treatment of the colon in cases of chronic appendicitis associated with colitis, a large proportion of which cases are so associated. He condemns most strongly the removal of the appendix through the smallest possible opening and the failure to explore the whole abdominal cavity when there have been chronic symptoms.

X-Ray Study of the Alimentary Tract.—H. W. Van Allen discusses the following conditions of parts of the alimentary tract which may be determined with the aid of the *x*-rays: position, general shape, motility, obstruction, areas of disease, and success or failure of operative procedures or usefulness of apparatus that may be applied.

Memorials to Thomas Dwight.—J. C. Warren, J. B. Blake, and D. Cheever record their tributes to the memory of the late professor of anatomy of Harvard University.

Cesarean Section for Placenta Previa.—J. G. Hanson reports the case of a multipara in whom a successful cesarean section was performed for a central placenta previa coexisting with a rigid undilated os.

Saratoga Springs.—History; Origin; Chemical Constituents; General Therapeutic Action. D. C. Moriarta.
Saratoga Springs; Specific Clinical Indications. G. F. Comstock.
Hypertrichosis; Its Treatment with the *X* Ray. S. Stern.
A Comparative Study of the Wassermann and Weil Cobra Venom Reactions for Syphilis. H. J. Schwartz.

Vertigo.—E. B. Dench classifies the cases of aural vertigo as follows: (1) Cases due to a chronic non-suppurative inflammation of the middle ear. (2) Cases due to a residual suppurative inflammation of the middle ear. (3) Cases due to aural suppuration. (4) Cases due to involvement of the auditory nerve trunk, as the result either of a specific inflammation involving the nerve trunk, or due to a degeneration of the end organ of the auditory nerve as the result of some middle ear inflammation or of some general diathetic condition. In the very large proportion of cases in which one can exclude specific disease or a neoplasm at the base of the brain, involving the auditory nerve trunk, a vertigo is due to some underlying disease of the middle ear or labyrinth.

The East River Homes.—H. L. Shively describes the group of tenement dwellings recently erected through private philanthropy in New York City, which dwellings are especially adapted to the requirement of tuberculous families and delicate persons liable to tuberculosis. As completed and now ready for occupancy, the East River Homes are four large fireproof buildings which will house 383 families in suites of from two to five rooms. There are 75 suites of two rooms, 212 of three rooms, 60 of four rooms, and 36 of five rooms. There are ample courts for air and light, to which access is had through passageways extending from street to street designed after the *Durchhäuser* of German and Austrian cities. These open passages insure a free circulation of air in all the courts. There are outside staircases in each of the four corners of the courts. The entire roof area of these sanitary homes is utilized for outdoor life and fresh air treatment. The roofs are fitted with loggias, open and partially enclosed toilet rooms, and comfortable seats, and upon an upper deck are spaces for open air drying of linen. Flowering plants and shrubbery to make the roofs as attractive as possible will encourage their fullest use by the tenants. On the façades fronting the park and streets are individual balconies on every floor, communicating with the bedrooms and living rooms by large triple hung windows.

Primary Degeneration of the Pyramidal Tract.—A. Gordon reports a case which presents from the clinical standpoint a classical type of Erb-Charcot spastic paraplegia, and from the pathological standpoint an exceptionally clear form of primary sclerosis of the pyramidal tracts.

Spa Treatment of Heart Disease at Nauheim and in America.—By L. F. Bishop. (See MEDICAL RECORD, Vol. 80, page 1304.)

Treatment of Gastric Disease at Carlsbad and Wiesbaden.—By H. G. Watson. (See MEDICAL RECORD, Vol 80, page 1304.)

Saratoga Springs.—By D. C. Moriarta. (See MEDICAL RECORD, Vol. 80, page 1301.)

Saratoga Springs: Specific Clinical Indications.—By G. F. Comstock. (See MEDICAL RECORD, Vol. 80, page 1302.)

X-Ray Treatment of Hypertrichosis.—S. Stern states that in cases in which one has to deal with a limited number of dark coarse hairs, the electrolysis treatment is still the method of choice and offers the best and quickest results; but in a patient with a great many hairs, sometimes involving practically the entire face, treatment by electrolysis offers very little relief. One cannot remove all the hairs; a great many keep on returning, and where the hairs are closely approximated one is bound to get a certain amount of scarring. By means of the *x*-rays it is a very simple matter after a certain number of treatments, to produce a complete alopecia of the part treated. The author has obtained brilliant results in the treatment of certain affections of the hair follicles, such as sycosis, trichophytosis, favus, etc. Then he has found that even after a complete alopecia was produced, if the treatment was then discontinued the hairs would generally return in two or three months, but if an occasional exposure was given for a certain length of time the alopecia could be made permanent.

The Wassermann and the Weil Cobra Venom Reactions.—H. J. Schwartz concludes that the Weil reaction seems to be specific for syphilis, with the sole exception of carcinoma. The Wassermann and Weil reactions do not run parallel, but are complementary to each other one proving sensitive under conditions in which the other fails. He believes that the application of the two tests, both in the diagnosis and treatment of syphilis, is highly important.

Case of Intussusception Complicated by Volvulus. C. S. Lawrence.

The Midwife Problem.—J. W. Williams states that the laity should be taught that poorly trained physicians are dangerous, that most of the ills of women result from poor obstetrics, and that poor women in fairly well-conducted free hospitals usually receive better care than well-to-do women in their own homes; that the remedy lies in the hands of the public, and that competent obstetricians will be forthcoming as soon as they are demanded. There should be an extension of obstetric charities—free hospitals and out-patient services for the poor and proper semi-charity hospital accommodations for those in moderate circumstances. The author also advises a greater development of visiting obstetric nurses and helpers trained to work under them and the gradual abolition of midwives in large cities and their replacement by obstetric charities. If midwives are to be educated it should be done properly and not in a makeshift way, and even then disappointment will probably follow.

Typhoid Bacillus Carrier.—C. Bolduan and W. C. Noble report an extensive epidemic of typhoid fever in the Borough of the Bronx and three wards of the Borough of Manhattan, in New York City. There were 300 cases, more than the average number occurring within these restricted limits. An investigation traced the origin to a certain dairy in Camden, N. Y. The conditions of the dairy were exceptionally clean, but there had been an undue prevalence in that village of typhoid fever also traceable to this dairy, the owner of which had had typhoid in 1863 or 1864; since that time there had been a number of cases in his family. The tests showed him to be a carrier, though he had not himself suffered in late years from the disease. The authors call attention particularly to the fact that milk may be infected by a chronic carrier, even though he is exceptionally careful. The dairy was kept much better than the average, but the occurrence of repeated infection from this source showed the danger. The dairyman died of "heart disease" last September.

Antityphoid Vaccination.—By J. M. Phalen. (See MEDICAL RECORD, Vol. 80, page 1203.)

Wassermann Reaction in Nonspecific Tumor of the Central Nervous System.—L. Newmark reports two cases presenting this association. He believes that while observations tending to diminish the diagnostic value of the Wassermann test should be regarded with circumspection, perplexing cases will sometimes occur. In such the interpreter will have to choose between some error in the complicated test or the existence of occult syphilis, as it would seem rash to question the specific nature of the reaction.

Treatment of Intestinal Amebiasis.—By W. E. Musgrave. (See MEDICAL RECORD, Vol. 80, page 97.)

Purin Content of Common Foods.—H. D. Arnold and R. C. Larrabee note that milk and eggs and all articles made from them are essentially purin-free. Vegetables are practically purin-free, but seeds contain a certain amount of purin in the plant embryos. A satisfactory method is to compare the foods according to the number of grams of purins in a kilogram of the food. Cod may be taken as the standard to determine the unit. There are about 0.5 gram of purin in one kilogram of cod. This amount may be considered as one unit. Grouping the foods according to the number of units one can construct the following classification: One unit: tripe, cod; two units: mutton, rabbit, halibut, pork, beef (ribs), ham, veal, and salmon; two and a half units: turkey, chicken, and beef (sirloin); four units; beefsteak; six units: liver; twenty units: sweetbreads (thymus).

Disorders of Purin Metabolism.—A. C. Reed and G. B. Wallace state that the meaning of the term uric acid diathesis has been gradually narrowed down until it includes only those diseases or clinical syndromes which are more or less connected with a pathological purin metabolism. Uricacidemia may be entirely independent of abnormal purin metabolism, but, nevertheless, variations in the amount of uric acid in the blood and urine are constant in the uric acid diathesis and can only be considered as due to a disorder of purin metabolism. The authors review the pathology of gout, the principal disease intimately connected with the uric acid diathesis, acidemia and urate deposition. They also point out how renal insufficiency may resemble gout and, in fact, the two conditions are often confused. Rheumatism is also confused with gout, but acute rheumatism seems entirely separate from primary purin disturbance. The fact that the major part of uric acid destruction normally occurs in the liver lends probability to the view that any disease-process limiting the functional power of the liver would seriously disturb purin metabolism, and this is supported by the occurrence of uric acid excretion in hepatic cirrhosis and acute yellow atrophy. It might also partly account for the uricemia often found in hepatic cancer. It is important to determine the tolerance of the patient to purin-free diet, but this is not sufficient alone. The endogenous as well as the exogenous purins have to be considered, and, as in the case of sugar in diabetes, it is highly important to ascertain the tolerance of the patient and increase it if possible. With the purin tolerance known the diet should be regulated to contain just under this value of purins.

Pernicious Vomiting of Pregnancy.—By C. B. Ingraham. (See MEDICAL RECORD, Vol. 80, page 105.)

Cacodylate of Soda in Enythema Multiforme.—W. Cuthbertson recommends the use of cacodylate of soda in all cases of erythema, more especially in those of the angioneurotic type.

Obsterics Among the American Indians.—F. Shoemaker states that the Indian women are becoming more and more in the habit of calling white medical assistance, and he reports briefly four cases, one of urethrovaginal fistula after labor with other complications, one of calcareous degeneration of the placenta, one of severe localized infection with high temperature, and the other a tedious twin labor lasting over four days and requiring active measures to bring it to an end. These cases, with others of like character which have come under the author's observation, suffice to show that Indian women are subject, like the whites, to serious accidents in the function of parturition.

Aneurysm of the Palmar Arch.—D. B. Robinson reports the rare case of a railroad switchman, aged 35, in whom, after a slight traumatism, an aneurysm, the size of a hickory nut or larger, developed at the center of the deep palmar arch. It was easily ligated and removed and recovery was uneventful.

Tonsil Hook.—L. F. Long has devised a new tonsil hook whose advantages are that a snare can be slipped on or off the tonsil without changing the hold on the tonsil after the hook is once placed. The hook, once placed, will stay in place and not drop out when pressure is relaxed, as a slight thickening on the lower two-thirds of the inner surface of the prongs holds it in place.

Knee-Joint Amputations.—C. E. Phillips states that his method consists in disarticulating the tissues of the knee, leaving the patella attached to the anterior flap.

sawing off its posterior surface and its sides with a bevel and fitting it into a notch between the condyles. The stump is very satisfactory. The patella forms its center and laterally the two condyles share their portion of the weight in such a manner that it is normally distributed as in the flexed knee, while the large bearing surface formed by the tough skin taken from the anterior aspect of the knee can bear the full weight of the body without abrasion or discomfort. Other advantages are the broader end surface and enlargement furnished by the condyles which will retain an artificial leg from slipping, and another is the short flap which is sufficient to cover the stump made by forcibly drawing down and fixing the patella, bringing with it the skin, fascia, and muscles, which, if allowed to retract, would fail to cover a still shorter stump.

Intussusception Complicated by Volvulus.—C. S. Lawrence reports the case of a male, aged *22*, who was subject to attacks of abdominal pain. His appendix had been removed at the age of 18, but without relief, and the attacks later increased in frequency. They were accompanied by nausea and vomiting, and in the attack reported there seemed to be obstruction, and the vomit was bad smelling. Operation was performed and an iliac intussusception with twisting on the mesenteric axis was found, the whole mass was removed, and the ends of the intestine were connected with a Murphy button.

Cancer of the Rectum and Its Treatment. P. Lockhart Mummery.
Radiography in Intestinal Stasis. A. C. Jordan.
A Case of Ruptured Extrauterine Pregnancy, with Remarks upon Diagnosis. I. B. Muirhead.

Cancer of the Rectum.—P. Lockhart Mummery believes that by far the most important predisposing cause of this condition is a simple growth in the bowel, such as a polypus or simple adenoma. Cancer of the rectum spreads by the lymphatics and by direct extension. Metastasis does not apparently occur early. Unfortunately there are no symptoms of any importance at an early stage. The earliest symptoms are a tendency to looseness of the bowels, a feeling as if the bowel was not completely emptied after an evacuation, and bleeding. Constipation is not as a rule an early symptom except in cancer high up in the bowel or in the large intestine, and even then it is uncommon. Other common symptoms are pain or discomfort in the sacrum and pain in the lower part of the abdomen. As regards the indication for operation, the author states that mere fixation of the growth does not always contraindicate removal. Extensive secondary glands, fixation by extension to other important organs, nodules in the liver, and the size or connections of the growth rendering it mechanically impossible to remove it, are, of course, contraindications.

Radiography in Intestinal Stasis.—A. C. Jordan states that intestinal stasis is a chronic disease due to the retention for too long a time of the intestinal contents and the toxic absorption resulting from this undue retention. The symptoms may be slight or severe, but they are very definite. They may be enumerated as follows: Abdominal pain, often severe; general depression and want of energy, which may be so extreme as to make life intolerable; poor appetite, with attacks of nausea or vomiting; a bad taste in the mouth; breath of an unpleasant odor; headache, backache, muscular pains, and aching in the joints; cold hands and feet and other signs of a poor circulation. Constipation is usually a marked symptom; often it persists in spite of all treatment, the patient being compelled to rely on purgative drugs and injections. Flatulence is always present and leads to attacks of abdominal distention. There is tenderness to pressure over the abdomen, especially in certain regions, of which the right iliac fossa is the most usual. The skin is stained, sometimes to a deep brown color; it feels unhealthy, as though wanting in elasticity; the sweat has a disagreeable odor. The breasts show changes such as are usually described as chronic mastitis; in more advanced cases cystic degeneration takes place, and the breasts are then in a condition in which a transition to cancer is very liable to occur. Similar changes are produced in other glands, and at operations on these patients chronic pancreatitis is found to exist; in many cases cholecystitis is present also and gallstones are very often found. Chronic intestinal stasis is frequently caused by kinks, in the diagnosis of which radiography is of the greatest assistance.

Ruptured Extrauterine Pregnancy.—I. B. Muirhead suggests that in a woman of childbearing age sudden severe pelvic pain, with pallor and collapse, is in itself sufficient to establish a diagnosis of rupture of an extrauterine pregnancy and to make immediate laparotomy imperative.

Varieties of Colitis and Their Diagnosis by Sigmoidoscopic Examination. P. Lockhart Mummery.
Vicious Circles Associated with Diseases of the Skin. J. B. Hurry.
Epidemic Poliomyelitis Occurring at Stowmarket. S. Hillier.
A Record of Some Cases of Epidemic Paralysis Occurring in Hampshire. G. F. England.
Epidemic Anterior Poliomyelitis in South Derbyshire. J. Hay Moir.
Retention of a Fetus in the Abdominal Cavity for Forty Years. E. Weatherhead.

Varieties of Colitis.—P. Lockhart Mummery states that colitis is at the present time a name which is very loosely used to describe a number of quite distinct conditions. Ulcerative colitis is a definite disease, characterized by severe and intractable diarrhea, profuse hemorrhage, and high temperature, and seriously threatens life. Follicular colitis appears to be a complication of other diseases, such as cancer and stricture of the colon. Tuberculous colitis is generally a late compliation of phthisis. Pericolitis, which causes a tight tubular stricture in some part of the colon, results from a slow fibrous change in the bowel wall. There are also a number of specific types, peculiar to tropical climates. Chronic mucomembranous colitis is not, as usually described, a clinical entity, but, on the other hand, is a collection of symptoms which, owing to want of better knowledge as to the pathology and physiology of the colon, have been placed together and labeled as a disease; whereas, in fact, these symptoms may result from a large number of entirely distinct pathological lesions, as follows: Kinking and partial obstruction of the colon from adhesions or pericolitis; dilatation of the colon and visceroptosis; chronic appendicitis; inflammation or displacement of the uterus or appendages; previous operations upon the abdomen resulting in adhesions; cancer of the colon; fibrous stricture of the colon; aneurysm of the abdominal aorta; and floating kidney. In about 45 per cent. of the cases there is a definite chronic inflammatory condition of the mucosa of the colon. There are three types of inflammation of the mucosa; the hypertrophic, the granular, and a third variety, in which the visible mucosa looks as if it had been sandpapered. A rare form of colitis is hemorrhagic colitis. A form of ulcerative colitis is often described as chronic dysentery. Another rare form is that caused by the bilharzia parasite. The author emphasizes the fact that chronic mucomembranous colitis should be considered not as a diseases, but as a symptom.

Vicious Circles in Diseases of the Skin.—J. B. Hurry enumerates these as follows: (1) Circles associated with inflammatory disorders; (2) circles associated with parasitic disorders; (3) circles associated with neuroses; and (4) circles associated with the appendages of the skin—hair, nails, sweat, and sebaceous glands. Examples of these vicious circles are seen in the following: Eczema

causes itching, which leads to scratching, which aggravates the eczema. Edema of the skin produces a loss of elastin, which diminishes the recoil of the skin, which increases the edema. In acne rosacea the increased pustulation causes an increase of the fibrous tissue, which leads to a retention of sebum, which increases the pustulation.

Poliomyelitis.—S. Hillier reports an epidemic of twenty-five cases of this disease occurring in Stowmarket, Suffolk, during the late summer of 1911.

Epidemic Paralysis.—G. F. England reports seven cases of this condition occurring in Hampshire during the fall of 1911. The cases were largely characterized by the predominance of meningeal symptoms.

Poliomyelitis.—J. Hay Moir reviews an epidemic of twenty-five cases of this disease that occurred in South Derbyshire during the summer of 1911.

Retention of Fetus.—E. Weatherhead reports the case of a woman 74 years of age who had been bedridden for many years. The abdomen was prominent, and a hard mass could be felt in the hypogastric region, rising up out of the pelvis. Part of the mass appeared on palpation to be of bony hardness and suggested a fetal head. It appeared to be tender to pressure. The patient complained of a good deal of pain at times, but her general health was fairly good for her age. Four years later she began to suffer from diarrhea with raised temperature and gradually sank, dying about three weeks later. A post-mortem examination disclosed the following: The tumor consisted of a nearly full-term fetus lying in the bag of membranes, which were more or less completely calcified. It formed an ovoid mass, which filled up the greater part of the pelvic cavity, the broader end of the ovoid being uppermost. The adjacent coils of intestine were intimately adherent to the sac and had to be peeled off, and the parietal peritoneum on the lower part of the anterior abdominal wall was also adherent. The uterus, flattened out by the tumor and atrophied, could be recognized lying in front of the lower part of the mass, with the inner ends of the Fallopian tubes and part of the broad ligament

Berliner klinische Wochenschrift.

December 25, 1911.

Antianaphylactic Properties of Leucocytes.—Massone combined leucocytes with anaphylactic toxin and showed that the latter was thereby disintoxicated. The toxin was prepared by Friedberger's method, which consists of cultivating the *B. prodigiosus* on agar for two days, washing the culture in normal saline solution, and combining it in decreasing amounts with definite quantities of guinea pig serum, which were allowed to stand for twenty hours in the ice box and afterward centrifugized, the supernatant fluid containing the toxin. The leucocytes were obtained in the usual manner from the peritoneal cavity of the guinea pig. When the combination was injected into the veins of the animals, it was shown that the anaphylatoxin had been either partially or completely neutralized. Leucocytes are therefore more than bactericidal. They are also antitoxic.

Power of Salvarsan Over the Wassermann Reaction.—Emanuel made the discovery that in the rabbit intravenous injection of salvarsan caused the Wassermann reaction to disappear for the time being. The normal rabbit, as is well known, reacts positively to the test. No lesson can be deduced from this result concerning the salvarsan treatment of human syphilis, but some light may be thrown on the nature of the reaction itself. The disappearance of the latter in man under salvarsan injections cannot be set down straightway to the curative effects of the drug, but rather to some power of the drug over the reaction. It has already been shown that both Hg and KI can cause the momentary disappearance or weakening of the normal rabbit positive Wassermann. In addition to rabbits, healthy goats react positively to the latter.

Successful Ligation of the Pulmonary Vein of the Left Lower Lobe for Shot Wound.—Heile reports the second case of this type, the first having occurred in von Eiselsberg's practice several years ago. The natural termination of these cases is death, rapidly ensuing. The patient was a boy who attempted suicide with a revolver discharged toward his heart. The first diagnosis was wound of the heart. The third and fourth ribs were immediately resected and the seat of the injury revealed. Suture seemed out of the question because of the inaccessibility of the lesion. In von Eiselsberg's case, however, it had been possible to close the wound directly. The author first succeeded in clamping the bleeding vessel, after which he placed upon it a double ligature. Aside from the threatening heart failure, the chest symptoms were out of all proportion to the severity of the case, being almost absent.

Treatment of Cervix Gonorrhea.—Wagner applies hot water to the cervix, using a special apparatus and technique. The water is maintained constantly at 45° C. and as much as 25 litres are allowed to irigate it under gentle pressure. A special speculum is used which distends the vagina. The patients are kept in bed during the treatment, which is administered daily, except during menstruation. Every eighth day the cervical mucus is examined for gonococci, and when the patient has remained free for a week she is not discharged as cured, but the treatment is continued until three consecutive negative weekly reports have been obtained. In a very large percentage of cases the patients are free from gonococci after four weeks of treatment. The latter is intended for recent cases only and largely as a prophylactic against endometritis.

Idiosyncracy to Röntgen Rays.—Schmidt mentions several examples of idiosyncrasy and supersensitiveness of the normal integument to the *x*-ray. This is manifested in several ways—erythema, burns of the first and even the second degree—which do not differ from the effects of an overdose in individuals not supersensitive When phenomena of this sort are noted, we cannot always be certain that an overdose is not at fault. Personally the author believes less in an individual over-susceptibility than in a natural variability in the resistance of any skin, in virtue of which there are certain days or times in which the skin is much more sensitive than at others.

Münchener medizinische Wochenschrift.

December 19 and 26, 1911.

Diagnosis of Perforating Aneurysm of the Cerebral Arteries.—Wichern cites the figures of Beadle published in 1907, which covered 555 cases, of which 411 were reported in the literature, while the balance were anatomical preparations from English hospitals and museums. Beadle wished to ascertain the likelihood of making a correct diagnosis during life and came to the conclusion that only rarely was this possible. Wichern therefore took up the problem, and his studies, chemical and other, led him to the following conclusions: Most of these aneurysms cause both general and focal cerebral symptoms, but in some cases show evidence which differs from that afforded by tumors in the narrower sense. Presumption of aneurysm increases with the existence of such etiological possibilities as arteriosclerosis, syphilis, and embolism. Especially suggestive of aneurysm is the recurrent or exacerbatory character of the symptoms, due to successive perforations. Lumbar punction is a differential diagnostiic resource of importance under certain conditions. If there is evidence

of repeated meningeal hemorrhages the diagnosis may be made outright, provided that this find is backed up by others.

Skiagraphy of the Digestive Tract.—Best and Cohnheim have sought to learn to what extent skiagraphy may be made to throw light on the digestion of certain foods. For some of the latter the research appears to furnish no data worth while. For example, in the digestion of meat it is impossible to learn when the stomach has become empty or when the chyme reaches the colon. Bismuth exerts a special activity in the small intestine which delays the progress of both solids and fluids and also induces reflex disturbance which prolongs the interval of emptying the stomach. It seems that barium sulphate does not possess these disadvantages. The röntgen investigation of digestion is of use in comparative work of any sort, but as an individual test would probably prove very untrustworthy.

Obstetrical Experience with Pituitrin.—Vogt of Professor Kehrer's clinic has tested pituitrin on an unusually large material. His conclusions, which in the main agree with those of contemporary clinics, are as follows: Pituitrin acts promptly and with certainty in the expulsive period. It serves to hasten normal labor and to antagonize secondary weakness of labor pains, both in normal and contracted pelves. Its action during the period of dilatation is inconstant, but may be efficacious in the individual case. Thus far it has not been shown that it aids in the expulsioin of the placenta. Pituitrin comes nearer being an ideal oxytocic than any remedy thus far known.

Conservative Management of Anthrax.—Wolff and Wiewiorowski report a number of cases in which good results were secured by simple conservative measures made up chiefly of antiseptic dressings. In some instances Bier's hyperemia was added, but in only one was there any use of knife, curette, or cautery. When we bear in mind that anthrax has as a rule been treated with the most heroic measures, justified as being life-saving, the new movement toward conservatism must be regarded as a notable advance. The patients were men who had come in contact with infected beeves or horses or with their hair. The diagnosis was always made through the discovery of the bacillus, as a rule strengthened with inoculation experiments. In one fatal case death was due to intestinal anthrax. It may have been a coincidence, but this seems to have been the only case in which the external lesion had been incised before the patient sought the clinic. The antiseptic dressings were of the simplest character—iodoform, boric acid ointment, moist compresses. In the sole case treated surgically the lesions were multiple and were excised. The patient, hitherto afebrile, developed high fever and delirium, but made a good recovery. Of thirteen cases treated seven would be classed as mild in type and six as severe. In ten cases the treatment was so conservative as to amount to a noninterference. The two worst pustules healed under boric acid.

Conjunctivitis and Rosacea.—Axmann refers to recent allusions to this clinical association, which seems to receive little attention in standard works. Unna mentions it and in some cases at least the two lessons do not represent a mere coincidence, for treatment directed solely to the rosacea appears to cause recovery from the conjunctivitis. It is, of course, possible that owing to the close proximity of the skin of the nose to the eyelids local treatment directed to the rosacea may make itself felt in the eyelids, while general measures intended to relieve the congestion of the nose would also favorably affect the conjunctiva. The author has found that the uviol rays directed to the nose exert at the same time a favorable effect on the eyelids, the nutrition of the latter being stimulated.

Deutsche medizinische Wochenschrift.

December 14, 1911.

Cancer of the Ovary at Five Years of Age.—Rosanoff of Moscow reports a case of this almost unique incidence. The child was attacked with pains in the abdomen, and a mass as large as the head of a newly-born infant was palpable to the right, between the pelvis and level of the umbilicus. The rapid growth of the tumor suggested malignancy. Laparotomy incision. The tumor was felt to have a pedicle, to wit, the right adnexa. It was extirpated and found to be a medullary carcinoma. The nearest approximation to this case is one of bilateral cancer of the ovary in a 14-year-old subject. Sarcoma of the organ in very young children is encountered in rare instances. The subsequent history of the case is not given and the report is much too sketchy for so rare an event.

Traumatic Appendicitis.—Sprengel, whose great work on appendicitis is a standard for reference, repeats here his disbelief in a traumatic type of the affection. A history of trauma is obtainable in a very small percentage of cases, such as could be set down properly to coincidence or mistaken diagnosis. Two cases are related which before operation appeared to be clean cut appendicitis of a traumatic etiology. One supervened twenty hours and the other thirty-six hours after a kick from a horse. Both were operated on radically at once. The first was found to be a rupture of the intestine requiring extensive resection. The perforation occurred near the cecum. In the second case the same diagnosis was made—abdominal contusion from a horse kick with possibility of traumatic appendicitis. Patient was found to have typical appendicitis, due to a fecal concrement with beginning peritonitis. There were no anatomical alterations which could be set down to trauma.

Peripheral Neurosis Due to Tobacco.—Von Frankl-Hochwart first mentions cases of neuralgia, due evidently to excessive smoking. He has notes of thirty-one cases of sciatica and twenty-two of brachial neuralgia. Diffuse pains, not restricted to individual nerve areas, were represented by 110 cases. The nature of these latter is obscure, as in some cases an arthopathy seemed to be present. In regard to a nicotine polyneuritis one must be noncommittal. The author has seen four cases in heavy smokers which could not have been due to alcohol or lues. A few cases have been reported by others. The condition termed by Erb *dyskinesia intermittens angiosclerotica* is abundantly recognized by its sponsor as occurring much more frequently in heavy smokers than in any other class of people. It is very largely a tobacco angioneurosis. The tremor and fibrillary twitching due to tobacco are well known. The nervous visceral affections due to nicotine comprise first of all cardiac irregularities of all kinds—palpitation, arrhythmia, pseudoangina pectoris. Respiratory phenomena of the same origin include dyspnea and Cheyne-Stokes breathing. There is possibly such an affection as pseudoexophthalmic goiter due to tobacco poisoning. The dyspepsia, loose bowels, and constipation due to tobacco are nervous in type. Tobacco is known to favor nocturnal pollutions and premature ejaculation, while many heavy smokers are more or less impotent.

Inhalations of Oxygen on the Elimination of Nitrogen and Sulphur by the Urine in Gout.—Carnevale Arolla Angelo has experimented on the value of inhalations of oxygen in the treatment of gout. The author concludes that the increased oxidation caused by the inhalations is explained by the increase of urinary nitrogen and the diminution of the non-ureic nitrogen, with a diminution of the nitrogen of the amido-acids. There is a slight increase of the uric acid. The inhalations exert a beneficial effect on the metabolism of the albumins.—*Rivista Critica di Clinica Medica.*

Insurance Medicine.

IRREGULAR EXAMINATIONS.

EXAMINERS, as well as physicians not regularly appointed by the company, have experienced a feeling of irritation at times at what seemed to them an unwarranted implication on the part of the company that they were incapable or unreliable, judging from the reluctance or even refusal to accept their examination when they have been party to what is termed an "irregular examination." The object of these few lines is to explain the situation in such cases so that the reader will have a better understanding of the matter and realize that in the great majority of cases the inquiries on the part of the company, or its request for a re-examination by the regular examiner, does not signify any reflection or criticism upon the value of the services which have been rendered.

A regular examination is one made by an examiner in good standing authorized to represent the company in the town where the applicant resides or does business. Irregular examinations may be divided into three classes as follows:

A.—Examinations in a place where the company has no medical representative and the agent is compelled to secure the services of the nearest available examiner, or of some local physician. In the latter case an inquiry is instituted to satisfy the home office that the physician is properly qualified and in good standing. In this class there is no alternative.

B.—Examinations made at some place other than the applicant's residence or place of business by an examiner regularly appointed for the former locality, although the company has an examiner at one or both of the latter points. An explanation is usually requested for irregularities in this class, and in most instances it is found that the applicant was visiting the place of examination on business or pleasure.

C.—Examinations made by an examiner outside of his own territory, or else by some physician not an appointed examiner, in a place where there is a regularly appointed examiner. The companies have strong objections to irregular examinations of this class and use all possible efforts towards preventing them.

Irregular examinations may be considered from three points of view:

First.—Life insurance companies will usually do their best, as they should, to keep the position of medical examiner as desirable and lucrative as the circumstances permit by cutting down the number of irregular examinations as well as by limiting the number of examiners. In Class A there is little or no choice in the matter, and most of the irregular examinations in class B are also unavoidable. In class C, however, there is small excuse for the irregular procedure, though it does occasionally happen that the regular examiner is positively unavailable through sickness, absence or the fulfillment of other urgent duties.

Second.—Irregular examinations in classes B and C may be the means resorted to by an agent, if he happens to be unscrupulous, of having an applicant with a certain impairment, such as a defective personal or family history, some physical weakness or bad habits, looked over by an examiner who is a stranger to the applicant and ignorant of the existence of anything detrimental to the risk, with the hope that the impairment will not be discovered; or, as will happen occasionally, even in the medical profession, the examiner may be known by the agent to be lax and careless in his work or willing to overlook the defect and is selected for this reason. An examiner should, therefore, always be on his guard and adopt extra careful measures when making an irregular examination in class B or C.

Third.—An irregular examination entails additional expense and correspondence, with a consequent delay of business, in order that the irregularity may be satisfactorily explained and the standing and ability of the physician, if not a regularly appointed examiner, properly established.

The irregular examinations under class C require further inquiry than those of the other two classes. In order to protect the interests of both the examiner and the company, it is a good practice in these cases, in addition to requesting an explanation from the agent, to communicate with the examiner regularly accredited to the place in which the examination was made, asking whether he was available at the time of the examination, whether the physician who made the examination, if not an appointed examiner, is competent, and whether he, the regular examiner, has knowledge of anything detrimental to the particular risk.

If, in such a case, the regular examiner has a clear recollection of the circumstances, and declares that he could have made the examination promptly, a re-examination executed in the regular way is requested unless the agent gives a satisfactory explanation of the transaction, in which case the irregular examination may be allowed to stand with an admonition, however, to the agent to confine his appointments to the regular examiner in the future.

Accident and Angina Pectoris.—One of the difficult questions as to what constitutes an accident under the Workmen's Compensation Act has just been decided in court with the assistance of a medical referee. A man let down a bucket of water into a sewer, which was carried by the current to the next manhole, about 80 yards away. Then, with the assistance of a winch, he pulled back the bucket against the current. Before beginning this work he complained of pains in his chest. After working for some time he stopped, again complaining of pain. His comrades saw that he looked very ill and placed him on some sacks, where he died. The doctor who made the post-mortem examination found that except for fatty degeneration of the heart the man was healthy. He concluded that death was due to angina pectoris and that there was no reasonable doubt but that there was a connection between the effort exerted in his work and the man's death. Evidence was given as to the severe nature of the work, and two physicians stated that there was no doubt that the strain accelerated death. But it was admitted that the man had had two attacks of angina before starting work, when there was no exertion to account for them. Evidence was given by a consultant that it was impossible to say whether the strain did or did not excite the attack, but in view of the fact that the man had had two previous attacks within a short time, independent of exertion, and that many attacks of angina had proved fatal apart from exertion, he thought that the fatal attack in this case was independent of strain. The opinion of the medical referee was against the applicant. In giving judgment against the applicant the judge laid stress on the fact that before starting work the man had had two other attacks, one in bed and the other while going to work.—London correspondence in the *Journal of the American Medical Association*, December 30, 1911

Book Reviews.

TRAITÉ PRATIQUE DES MALADIES DU COEUR ET DE L'AORTE. Par ERNEST BARIÉ, médecin de l'hôpital Laennec. Troisième édition entièrement refondue. Preface par le Professeur POTAIN, Membre de l'Institut. Prix 20 fr. Paris: Vigot Frères, 1912.

THIS volume is a complete treatise on the diseases of the heart and of the aorta, both functional and organic. It is divided into nine parts, the first dealing with the various methods of examining the heart and vessels, the latest methods, such as polygraphic tracings, electric cardiograms, blood-presure apparatus, etc., being discussed. This section occupies over 175 pages. The next 75 pages are devoted to diseases of the pericardium, and then affections of the endocardium, of the myocardium, complications of cardiac disease, functional disturbances of heart action, angina pectoris, diseases of the aorta, and, finally, therapeutics of cardiovascular disease, are fully considered. Yet with all this wealth of subject matter the volume remains a practical textbook, for discussions of debatable subjects are avoided and our knowledge of cardiovascular disease is classified as much as possible. Many divisions are discussed at length that in other similar books find but scanty mention. Among such discussions we note chapters on the heart in diabetes, in gout, in chronic renal affections, in tabes, etc. Of course, French authorities are quoted for the most part, but German investigators are not forgotten by the author and such pathfinders among English clinicians as Mackenzie are given due credit. A very useful innovation is a complete topical review of the subject matter which ends each chapter. The book is well printed and is illustrated mostly by semidiagrammatic line drawings, which are much clearer than, though perhaps not so imposing as, the usual half-tone reproductions of American textbooks. We think its perusal should prove very profitable to the American physician, whose medical education usually accentuates German writings and research to the neglect of the French.

ANORMALE KINDER. Von Dr. Med. L. SCHOLZ, Direktor der provinzial-Irren und Idiotenanstalt in Koster (Prov. Posen). Price 10 marks. Berlin: Verlag von S. Karger, 1911.

WITH characteristic German thoroughness the author presents in this volume a study of the atypical child. This is intended for parents and educators, and for directors and teachers in schools for defective children, reformatories, and other corrective institutions. This treatise contains a description of the various forms of mental deficiency in the young, with their diagnosis and treatment.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. Herausgegeben von Dr. L. KATZ, Spezialarzt für Ohren-, Nasen-, und Halskrankheiten in Kaiserslautern; Dr. H. PREYSING, Prof. der Ohrenheilkunde, Ord. Mitglied der Akad. für Prakt. Medizin zu Köln a. Rh.; und Dr. F. BLUMENFELD, Spezialarzt für Nasen-, Hals-, und Lungenkrankheiten im Wiesbaden. 1 Bd., 1 Hälfte, Lief. 7 and 8. Price 9 marks. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1911.

PREVIOUS parts of this work have already been reviewed in the MEDICAL RECORD. The present number contains the following topics: the topographical anatomy of the pharynx, neck, and mediastinum, by J. Sobotta; the lymphatic apparatus of the head and neck, by August Most; and the beginning of the article on the elements of general anesthesia, by R. Haecker. As in the previous numbers, this installment is profusely illustrated with plates and photographic cuts that represent the best work that has been accomplished in this field.

THE REPORT OF THE PHILADELPHIA MILK SHOW. Its Organization and Management, and a Description of the Exhibits. Edited by ARTHUR EDWIN POST, Bureau of Municipal Research; Executive Secretary Philadelphia Milk Show. Illustrated. Published by the Executive Committee, 1911.

THIS report, profusely illustrated with photographs of exhibits, charts, programs, posters, invitations, advertisements, etc., presents a complete description of the Milk Show which was recently held in Philadelphia and which demonstrated, like the Child Welfare Exhibits held in New York and Chicago, that this means of educating the community has passed the experimental stage. This report is meant to save future promoters of similar undertakings the necessity of passing through the same stage by experimentation in solving the problems of organization.

JUCKENDE HAUTLEIDEN. Von SANITÄTSRAT Dr. S. JESSNER, Königsberg i. Pr. Vierte umgearbeitete Auflage. Price 2 marks. Würzburg: Curt Kabitzsch, 1911.

PRURITUS as a symptom is one for the relief of which the dermatologist is more frequently called upon to prescribe than for anything else. In this pamphlet the author treats exhaustively of the subject of pruritus and presents many prescriptions available for its different forms. For most of his ointments he uses a base known as "unitin" which is a superfatted emulsion containing a substance similar in composition to blood serum.

ORTHOPEDIC SURGERY. By EDWARD H. BRADFORD, M.D., Surgeon to the Boston Children's Hospital; Consulting Surgeon to the Boston City Hospital; Professor of Orthopedic Surgery, Harvard Medical School; and ROBERT W. LOVETT, M.D., Associate Surgeon to the Boston Children's Hospital; Surgeon to the Infants' Hospital, the Peabody Home for Crippled Children, and the Massachusetts Hospital School for Cripples; Assistant Professor of Orthopedic Surgery, Harvard Medical School. Price $3.50. New York: William Wood & Company, 1911.

THE subject of orthopedic surgery is one that touches closely the work of the general surgeon, the general practitioner, and the pediatrist. It is a subject, moreover, in which, perhaps more than in any other branch of medicine, there is required an exact knowledge of anatomy and pathology, as well as an appreciation of mechanical laws and their application. No branch of the medical art has reached a higher stage of development than has that of orthopedic surgery, and no men have contributed more to this advancement than have Bradford and Lovett, whose writings have received worldwide recognition as authoritative utterances. It is a pleasure, therefore, to welcome a new book from the hands of these authors. The present volume is an entirely new work, supplying a demand for a condensed handbook for the use of students and practitioners. Controversial matter is omitted, and only the accepted opinions as to the nature and treatment of various orthopedic affections are presented. This work is eminently a practical one, embodying the results of thirty years of clinical work in the Boston Children's Hospital. Among the many excellent chapters in this work may be mentioned the one describing the orthopedic treatment of infantile paralysis, a subject that has acquired, in view of recent widespread epidemics, considerable importance. The art of photographic illustration has reached its climax in the manner in which it has contributed to the value of this work. In clearness and in elegance the numerous illustrations which supplement and elucidate the text leave nothing to be desired. These, together with the excellence of typography, paper, and binding, combine to make this volume an example of consummate workmanship.

MEINE PRÄPARATIONSMETHODE DES OPERATIONSFELDES MITTELS JODTINKTUR. (Disinfection of the Operative Field with Tincture of Iodine.) By Dr. ANTONIO GROSSICH, Head Surgeon of the Ospedale Civico in Fiume, Austria. Price 75 cents. Berlin: Urban & Schwarzenberg; New York: Rebman Co., 1911.

THE feeling of general contentment which followed the apparent success attending the various methods of skin sterilization that have been developed during the past few decades seems to be shattered in part by the claims made by those advocating the so-called iodine method of preparation before operations. One of the names most intimately associated with the development of this procedure is that of the author of the above booklet, who is so sufficiently impressed by the worth of this method that he has employed it exclusively in almost every surgical condition. Thus he states that in a series of 3,759 cases the iodine method was used to the exclusion of every other method of disinfection, including preliminary washing with soap and water or other methods. The writer does not believe that the use of the ordinary 10 per cent. tincture of iodine is followed by irritating or other deleterious effects and makes the very bald statement that his personal clinical experiences have shown that tincture of iodine used on the dry skin properly shaved, but not washed, prevents every possibility of infection from the wound. The booklet herewith noted contains the author's papers on the subject of iodine disinfection, which have appeared in the medical journals and also a bibliography of all the references by other writers. Notwithstanding the claims made for the procedure it will probably be a long time before surgeons will entirely disregard the lessons and good results of the past with the already accepted methods of skin disinfection, but we must grant that the results thus far achieved are certainly worthy of close attention.

COLLECTED PAPERS BY THE STAFF OF ST. MARY'S HOSPITAL (MAYO CLINIC) FOR 1910. Price, cloth, $5.50 net. Philadelphia and London: W. B. Saunders Company, 1911.

CLINICAL and scientific papers from the Mayo clinic at Rochester are always received with pleasure, for the reader is sure to find therein the results of deep thought, vast experience, and able, logical reasoning. The present volume is a collection of papers by the staff of St. Mary's Hospital, Mayo clinic. These contributions have been previously published in various journals, and they are so full of valuable knowledge that it is indeed fortunate to have them so easily and readily accessible. It is difficult in this short review to enter into the merits of the various papers. Especially important are those dealing with the chronic types of appendicitis, diverticulitis of the lower bowel, intestinal obstruction, pyelograph, goiter, and the notes on Italian surgery.

A RADIOGRAPHIC ATLAS OF PATHOLOGIC CONDITIONS OF BONES AND JOINTS. By AMEDÉE GRANGER, M.D. Price $6.00. New York: The A. L. Chatterton Co., 1911.

THE knowledge of abnormal conditions of bones and joints afforded by the Röntgen ray is truly enormous and we are becoming more and more dependent upon it in making diagnoses of diseased states of these organs. To get the full value of this method of examination it is absolutely necessary that the radiogram should be taken and interpreted by an expert. The former presupposes skill and experience in operating the *x*-ray machine, the latter a keen eye and immense experience with the pictures of normal and abnormal conditions.

A radiographic atlas is designed to aid the less expert in interpreting the radiogram, and this the present work succeeds in doing in a limited way. The introductory remarks of the author, as well as the chapter on skiagraphy, are excellent and full of valuable suggestions. The plates show the normal and diseased conditions of bones and joints quite well and their reproduction is good. The atlas, however, can scarcely be called a complete one, for only advanced states of disease are pictured. Thus the early changes in the epiphyseal ends of bones in tuberculosis are not at all given, and yet these are most important in the early diagnosis of such disease. Again, in the very important subject of osteomyelitis, the author makes no mention of the changes in bone structure occurring in the acute stages of this disease.

Altogether the atlas is a good one; it affords excellent pictures of the normal, diseased, and injured bones and joints and should be of value to the physician and the surgeon.

DIE ERÖFFNUNG DER SCHADELHÖHLE UND FREILEGUNG DES GEHIRNS VON DER NEBENHÖHLEN DER NASE AUS. By Professor Dr. A. ONODI, Director of the Königl. Universitätsklinik für Nasen- und Kehlopfkrankheiten, in Budapesth. With 134 Illustrations in the Text and 89 Plates. Price, 8 marks. Würzburg: Curt Kabitzsch, 1911.

THE above is a reprint from the *Zeitschrift für Laryngologie, Rhinologie, und ihre Grenzgebiete*, and presents in a most complete form the methods of exposing the cranial cavity and the brain through the medium of the accessory sinuses of the nose. The text, itself, is mainly in explanation of a series of 89 excellent plates which present the anatomical landmarks and dissections of this region. The book must be of undoubted value to those directly interested in this field of surgery, which has recently become so largely developed.

THE OPHTHALMIC YEAR BOOK, VOLUME VIII. By EDWARD JACKSON, M.D., Professor of Ophthalmology in the University of Colorado; THEODORE B. SCHNEIDEMAN, M.D., Professor of Ophthalmology in the Philadelphia Polyclinic; WILLIAM ZENTMAYER, M.D., Attending Surgeon to the Wills Eye Hospital, Philadelphia. Illustrated. Denver, Col.: The Herrick Book and Stationery Company, 1911.

THIS number of the Year Book is a decided improvement on its predecessor, corresponding with the improvement noted in each volume of this work as it has appeared. This volume is considerably larger than that of 1910. Its 455 pages are replete with accessible information of value to all who are engaged in the practice of ophthalmology. One marked improvement is the printing of the names of authors in bold type in the body of the text. In the preface the author states that "up to the present time the subscribers to the Ophthalmic Year Book have not paid the cost of printing and distributing it. While it is no unusual manifestation of enthusiasm for the originator of such an undertaking to do all he can to make it a success this cannot be relied on for a permanent basis of support." Giving as it does a terse, succinct, and complete review of all that is of value in the current literature of ophthalmology and a complete yearly bibliography, English-speaking ophthalmologists cannot afford to permit the publication to lapse. The reviewer would counsel its substantial support by all who are interested in this branch of medicine.

A SYSTEM OF MEDICINE. By Many Writers. Edited by Sir CLIFFORD ALLBUTT, K.C.B., M.A., M.D., LL.D., D.Sc., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Caius College, and HUMPHRY DAVY ROLLESTON, M.A., M.D., F.R.C.P., Senior Physician, St. George's Hospital, Physician to the Victoria Hospital for Children; some time Fellow of St. John's College, Cambridge. Vol. VIII. Disease of the Brain and Mental Diseases. Price, $6.00. New York: The Macmillan Company, 1911.

THIS volume continues the description of the diseases of the nervous system. In its arrangement it differs from the corresponding volume of the first edition in that it does not contain the diseases of the skin, but is concerned entirely with the diseases of the brain and mental disease. Dr. Batten has contributed a new article on meningitis, but does not deal with the tuberculous form, and has also written a new article on acute polioencephalitis. Other new articles are by Prof. J. Michell Clarke on recurrent paralysis, by Dr. James Collier on apraxia and agnosia, and by Dr. Head on occupation neuroses. The article on neurasthenia by Sir Clifford Allbutt has been largely rewritten and expanded. The volume opens with an able article on the experimental pathology of the cerebral circulation by Mr. Leonard Hill, in which, among other valuable facts, the following of practical interest to those who use chloroform for anesthetic purposes is noteworthy: If the heart be weakened by some poison, such as asphyxial blood or chloroform, the sudden dilatation of the right ventricle produced by the assumption of the feet-up position, or by pressure on the abdomen may throw the heart into paralytic dilatation. The veteran authority on nervous diseases, Sir William Gowers, contributes an illuminating article on epilepsy, and Dr. Risien Russell is responsible for several papers. One of the clearest and best articles of the book is that by Sir Clifford Allbutt, who combines in an eminent degree accurate knowledge and the faculty of expressing himself with a highly distinctive literary style. Dr. Head discusses the occupation neuroses and his paper is perhaps the best brief presentation of the subject in the English language. Dr. Mercier, another writer with a wide command of the English language and a master of apt phraseology, deals with vice, crime, and insanity. The author believes that, while as a rule the criminal is not like the poet, born and not made, as so many European writers insist, yet that there are some criminals born with a congenital inability to become moral, just as others are born with a congenital inability to grow to adult stature, or to develop a complete palate or lip or spinal canal. In his chapter on epochal insanities Dr. Houston objects to the term dementia precox invented in Germany and used there and in this country as covering a considerable part of the "adolescent insanity." He recognizes that the term represents a clinical type, but brings several objections against its employment, one of which is that many of the cases placed under the head of dementia precox are described as curable, and in the opinion of Houston the word "dementia" should never be used to indicate a form of mental disease that can be recovered from. This book maintains the high standard of the preceding volumes and affords an excellent exposition of the rational and somewhat conservative views of the most prominent British alienists.

LOVE AND LETTERS. By FREDERICK ROWLAND MARVIN. Price, $1.50. Boston: Sherman, French & Co., 1911.

DR. MARVIN, whose varied career has included law and theology, as well as medicine, has given us in this book a series of random essays upon topics which are of general interest and yet which are not in any definite sense related to each other. The titles of these essays are: Love and Letters, from which the book derives its name; the Good Neighbor, Silence, Noble Deeds of Humble Men, The College and Business Life, Old Age and Culture. The essays are all remarkable for the amount of culture and erudition which they show, and are really records of a gifted man's excursions among books, for the thorough study and digestion of which the author has fortunately had sufficient leisure.

Transactions of the American Gynecological Society. Volume 36, for the year 1911. Philadelphia, 1911.

This volume records the minutes of the proceedings at the thirty-sixth annual meeting of the American Gynecological Society, which was held at Atlantic City in May, 1911. As practically all of these papers have appeared in the periodical literature they have, in greater part, been reviewed; but in addition the volume also contains the discussion of the papers by the members at the time of the meeting. During the three days' session a total of thirty-five papers was read, noteworthy among which were the following: Vaginal cesarean section in the treatment of eclampsia. The treatment of placenta previa. A study of the blood supply of uterine myomata, Renal decapsulation in eclampsia, and a number of studies on the surgery of the ovary.

A Text-Book of Meat Hygiene, with special consideration of ante-mortem and post-mortem inspection of food-producing animals. By Richard Edelmann, Ph.D., Medical Counselor, Royal State Veterinarian of Saxony, Professor at the Royal Veterinary High School in Dresden. Authorized translation revised for America by John R. Mohler, A.M., V.M.D., Chief Pathological Division U. S. Bureau of Animal Industry, and Adolph Eichorn, D.V.S. Senior Bacteriologist, Pathological Division, U. S. Bureau of Animal Industry. Second Edition. Price $4.50 net. Philadelphia and New York: Lea & Febiger, 1911.

The vital importance of healthy meat as wholesome food, the great size of the industry concerned in its preparation, and the strict enforcement of our comprehensive laws on the subject have created a demand which has called forth a second edition of Edelmann's authoritative work. The methods of production, preparation, and conservation of meat, the United States Regulations governing meat inspection, and the various diseases discoverable in meat are all fully covered. The book can be considered as an official guide, and, while a necessity to inspectors, will be found of great interest to physicians and veterinarians. It is excellently printed and bound, and contains numerous illustrations.

Microbiology for Agricultural and Domestic Science Students. By Many Contributors. Edited by Charles E. Marshall, Professor of Bacteriology and Hygiene, Michigan Agricultural College. Price $2.50 net. Philadelphia: P. Blakiston's Son & Co., 1911.

This volume contains such an immense amount of material that any adequate review in the space permitted is well-nigh impossible. Following a very complete and detailed consideration of the Morphology, Culture, and Physiology of Microorganisms, the main body of the book is devoted to Applied Microbiology. Here the organisms peculiar to air, water, sewage, soil, milk, and milk products are carefully considered and the way is pointed out by which proper use is to be made of this knowledge. The Microbiology of Special Industries forms another division and the remainder of the book is devoted to the microbial diseases of plants, man, and animals. As can be appreciated, the ground covered is enormous, and the task of editing the work of the nineteen authors covering it has been difficult. This task, however, has been well accomplished and the slight lack of unity is fully compensated for by the value of the material offered. The practical man in Agriculture and Domestic Science will find in it a formulation of the basic principles upon which he must complete that amalgamation of practice and science, already begun, which is necessary for his proper and logical development. There is also much information of value for the physician, the sanitarian, and the veterinarian. The book can be freely recommended as containing a comprehensive and able consideration of the subject.

Anæsthesia and Analgesia. By J. D. Mortimer, M.B. (Lond.), F.R.C.S. (Eng.) Anesthetist, Royal Waterloo Hospital, Throat Hospital Golden Square, St. Peter's Hospital for Stone, etc. Instructor Medical Graduates' College. Price $2.00. London: University of London Press, 1911.

The difference between medical practice in this country and in England is well illustrated in this volume, an addition to an already long list of textbooks on a well-treated subject. The results from the use of ether, either alone or preceded by chloroform or nitrous oxide, have proved so satisfactory to the great bulk of the medical profession in the United States that they will not heed the author's strong advocacy of chloroform. The chloroform-ether mixture they are almost wholly unacquainted with, and are not liable to adopt. All history and pharmacology have been omitted, but the preparation and after-treatment of the patient, the selection of the anesthetic, and the difficulties peculiar to certain operations have been rather fully considered. The author fails to condemn the elicitation of the corneal reflex, which is a rather important point if the patient is to escape sore eyes. Also he cannot be conversant with recent work in obstetrics when he does not advise against the use of chloroform in eclampsia. The pathology of delayed chloroform poisoning is very inadequately presented. On the other hand, most of the operations are well considered and there is a good chapter on the medico-legal position of the anesthetist.

Diseases of the Stomach. A Textbook for Practitioners and Students. By Max Einhorn, M.D., Professor of Clinical Medicine at the New York Post Graduate Medical School and Hospital; Visiting Physician to the German Hospital. Fifth revised edition. Price $3.50. New York: William Wood and Company, 1911.

Dr. Einhorn's textbook on diseases of the stomach is perhaps the most favorably known volume on the subject in the English language. Its preeminence is due to the fact that it is written by a man with absolutely first-hand knowledge of the subject, whose many contributions to the periodical medical literature have greatly increased our knowledge of gastric functions in health and disease.

The present edition of the book is especially full in descriptions of the methods and apparatus used in examining the digestive functions. Much of the apparatus has been originated or first systematically used by Dr. Einhorn himself; the duodenal pump is one of the latest of these and we predict that much light will be thrown upon the digestive processes by the results obtained with this instrument in the next few years. Radiography is given a more prominent place in this edition in accordance with the rapid strides made by this method of examination of the stomach. The clinical pictures of gastric disease are very clearly defined, but the therapeutic indications and methods are especially fully treated. We like the moderate conservativeness of the author especially in the consideration of such subjects as splanchnoptosis, movable kidney, etc.; to Einhorn surgical treatment in such and similar conditions is the last resort, as it should be, and not the first therapeutic measure.

A good textbook is a *sine qua non* of success in diagnosis and treatment of gastric disease and we heartily recommend Einhorn's work to students of medicine and to physicians looking for such a book.

Reproduction in the Human Female. The Uterine Mucosa in the Resting, Menstrual, and Pregnant States, and the Function of the Decidua. Incorporating an Account of an Early Human Ovum. By James Young, M.D., F.R.C.S. (Edin.); Physician to the Lauriston Prematernity Home; Gynecologist to the St. Savior's Dispensary, and late Tutor in Clinical Surgery, Royal Infirmary, Edinburgh. Price 21 shillings. Edinburgh and London: William Green & Sons, 1911.

This work is the product of original investigation. It presents an account of the structure of the uterine mucosa and of its changes during menstruation and pregnancy. Many erroneous views on this subject are laid bare, and for the first time it is shown that the structure and modifications of the uterine mucous membrane are adapted to the functions of menstruation and of fetal nutrition. Thus the author demonstrates that the vessels are so constructed as to permit a ready opening up of their walls, and that the stroma is of such structure and consistency as to be readily displaced by fluid or blood. The scope of this work is indicated by the following chapter headings: structure of the uterine mucous membrane; menstruation; mode of action of fetal structures on the maternal tissues, twofold action of chorion, pregnant tube; placental fragments and chorionepithelioma; description of very early human ovum, explanation of the uterine changes in pregnancy; extrachorionic and intrachorionic action of the fetal cells; and structure and function of the decidua. There is an appendix on edema and a bibliography. Of the above topics special mention may be made of the very early human ova, described by Peters and others, including one first described by the author. The text is elucidated by means of twenty full-page colored plates and sixty-eight photographic illustrations. These are all collected in the back of the volume and constitute, in their clearness and beauty, one of the important features of this work. By virtue of its originality this represents a valuable contribution to the sciences of obstetrics and gynecology.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Twenty-fourth Annual Meeting, Held in Washington, D. C., December 12, 13, and 14, 1911.

THE PRESIDENT, DR. RUDOLPH MATAS, OF NEW ORLEANS, LA., IN THE CHAIR.

(*Concluded from page 99.*)

Postoperative Gastric Dilatation.—Dr. T. C. WITHERSPOON of Butte, Montana, stated that in three of his cases a marked dilatation of the stomach existed without obstruction. No portion of the intestinal tract was similarly dilated. There was no infection of the surgical field and visceral union was perfect. Unlike the case reported in his former paper, there was good union in the parietal wounds of the last two. Neither of these patients suffered pain without the epigastrium, as did the first patient. He was impressed with the idea that in the former the segmental trophic disturbance manifested itself in both visceral and somatic nerves, while in the latter case in the visceral nerve distribution alone. In all three cases the paralysis of the stomach, the freedom from mechanical interference with movements of and emptying of the organ, the purely local nature of the dilatation, the lack of any demonstrable wound infection and the distinct segmental character of the trophic disturbance seen in the first patient seemed to point distinctly to a central paralysis. Twice in the last two years he had had an opportunity to demonstrate the distinctly protective value of colon bacillus vaccination before operating. The two patients had had abdominal operations performed, and each suffered seriously from vomiting and gastric dilatation, which necessitated lavage, and they both suffered likewise from urine shut off for twenty-four or forty-eight hours. Both feared a second operation, and especially as the nature of the procedure was to be more serious. He thought it wise to at least immunize against the common source of bowel intoxication and, therefore, vaccinated against the colon bacillus until two hundred million caused no reaction. The result was a recovery after operation, without nausea or meteorism in any part of the intestinal tract. While the two instances demonstrated nothing of scientific value, they nevertheless pointed a way and opened a field for inquiry.

Postoperative Dilatation.—Dr. GEORGE A. HENDON of Louisville, after reporting two cases of postoperative gastric dilatation, drew the following conclusions: 1. The essentials in the pathology were not known. 2. The most plausible theories were (a) kinking of the lower duodenum under the mesentery, causing a mechanical obstruction, and, as a result, hypersecretion and the paralysis of overdistension; (b) some unfamiliar toxins caused paralysis of the muscular walls and resultant hypersecretion and retention. This caused the organ to become heavy and to sag down, thus producing the duodenal kink. 3. There was a deadly toxin generated, either as the cause or the result of the dilatations, which had a peculiar and powerful depressing effect upon the vital organs. 4. That in the treatment we should not wait for vomiting to appear before becoming active. 5. The stomach tube was the only reliable means for relief. 6. That obscure and alarming symptoms affecting the abdomen after surgical operations should be investigated through the stomach tube.

Lymphatic Edema and Elephantiasis.—Dr. ALBERT VANDER VEER of Albany reported a case of lymphatic edema, which was possibly congenital in character, in a woman, forty years of age. Careful attention was given to her general health, as much rest as possible advised, and pressure, by means of bandages, was applied from the toes up to the groin. This afforded relief, but when removed the general edema would return. Operative intervention was not attempted at any time. Since observing this patient he had seen a few cases of distinct lymphatic edema of the lower extremities, each one complicated with enlargement of the scrotum and vulva, several arm cases following removal of the breast in a female, and one in a young woman without tumor or operation. The second case was one of elephantiasis in a woman, seventy-two years of age. Case three was one of marked lymphatic edema of the left arm extending from the finger tips to the shoulder, following an operation for the removal of the left breast. Case four was one of lymphatic edema of the right leg. Ligation of the femoral artery in Scarpa's space was performed. The patient did well, but there was not much diminution in the size of the leg or permanent improvement. A year later ulcers appeared, and amputation was done to the middle third of the thigh. The patient convalesced nicely and was very much more comfortable afterwards, but ligation of the artery did not bring the desired relief. Other cases were reported by Dr. Vander Veer, with comments.

Indications for Abdominal Cesarean Section in Eclampsia.—Dr. JOHN F. MORAN of Washington, D. C., reported four cases of eclampsia which occurred in two patients he saw in consultation, in which cesarean section was performed, saving both mothers and all of the children. The first patient, a primipara, eight months gestation, frequent convulsions, cervix intact, was operated upon by Dr. I. S. Stone, and the second was operated upon at term under like conditions, in three successive labors, by Dr. W. P. Carr. Kellitz, in 1897, collected 28 cases of eclampsia operated upon by cesarean section with a maternal mortality of 50 per cent., and an infantile mortality of 62 per cent. Streckeisen, in 1903, collected 28 cases; 12 mothers died and 9 infants were dead, or died shortly after birth. Hillman, in 1809, collected 39 cases and reported one of his own, giving a mortality of 50.5 per cent. for the mothers and 43.2 per cent. for the infants. All but seven of these cases were previously reported by Kelly or Streckeisen. The speaker had collected 53 cases, including the four herein reported, operated upon from 1901 up to the present time. Seventeen mothers died, a mortality of 32.32 per cent. Forty-five infants were born alive, seven were stillborn and four were not mentioned. Altogether, 116 cases had been reported, with a maternal mortality of 40 per cent. While the statistics of the last decade showed a marked improvement over the previous one, the mortality still was far above the general death rate of eclampsia. A careful analysis of the cases, however, showed that many of the patients had been subjected to other methods of treatment and were moribund at the time of operation. Abdominal and vaginal cesarean section were not proposed as substitutes for the other methods of intervention in eclampsia, but the claim was made that they had a well defined field of application in certain cases of eclampsia. If they were to have an established place in the treatment of this complication, the indications for which they were urged must be met by prompt elective action, for to delay until the patient was *in extremis* and all other treatment had failed was to invite disaster.

The Indications for and the Limitations of the Lane Operation.—Dr. JOHN YOUNG BROWN of St. Louis said that during the last three years he had operated on sixteen carefully selected cases of this type. In all of these cases a diagnosis had been arrived at by a process of exclusion, and in each intestinal stasis had been demonstrated by means of the bismuth meal prior to operation. A long incision through the right rectus sufficient for

general exploratory purposes had been made. The ileum had been divided six inches above the ileocecal valve, and both proximal and distal ends closed, a lateral anastomosis then being made between the ileum and sigmoid. Prior to this, a general exploration of the abdomen had been made and such work done as the individual pathology would indicate. Of the sixteen cases operated on, fourteen presented well defined pericolic membranes, and in all there was present kinking of the ileum. In two of the cases the condition found at operation was undoubtedly due to primary involvement of the appendix. In nine of these cases the constipation and the symptoms of intestinal toxemia had been entirely relieved, the patients gaining in weight and showing marked general improvement. In five of the fourteen cases, while the improvement had been satisfactory, much annoyance had resulted from gaseous distention and pain in the excluded cecum and colon. These were the type of cases in which Mr. Lane advocated a secondary operation, which operation should consist of the removal of the colon down to the sigmoid. It could not be too strongly emphasized that neither the Lane operation nor any of the suspension operations should be undertaken unless there were well defined demonstrable pathological lesions justifying their performance. All so-called atonic and neurasthenic types of enteroptosis would yield far better results if given proper rest, hygienic and dietetic treatment.

Parathyroids and Their Surgical Relation to Goiter.—Dr. CHARLES H. MAYO and Dr. BERNARD F. MCGRATH of Rochester, Minn., said it was known that the parathyroids were concerned in the metabolism of the body, but definite knowledge of their physiological function and pathological importance was yet very limited. Many diseases had been attributed to these glands without having had their etiological relationship supported by scientific investigations. Experimentation and clinical and histological examinations had shown a connection between the parathyroids and tetany. Recent investigations had proven that pathological processes in the thyroidal tissue produced hyperplasia with resultant hypofunction, especially in the presence of a contributing factor, as, for example, gastrointestinal disease. Hemorrhages, which probably occurred in the glands during labor, were given as one of the causes of the pathological processes. It was stated that tetany did not take place at the time of bleeding because the brain of the newborn was not sensitive, owing to the larger content of calcium. The attacks rarely occurred before the third month. Defective calcium metabolism had been noted in experimental tetany. Histological examinations had shown a relationship between the parathyroids and tetania gravidarum. Cases of tetany associated with congenital syphilis, in which the parathyroidal tissue was hypoplastic, had been cited. Some authorities held a morphological similarity and interrelation of function between the parathyroids and the thyroid gland. In operations on the thyroid, the variable size, location, appearance, and condition of these little bodies should be kept in mind. If such a mass be accidentally removed, it should at once be implanted beneath some part of the capsule. Parathyroidal tissue was sometimes present within the thyroid, in which case it could be injured in a simple operation on this gland. It had a large factor of safety. Postoperative tetany was rare. In 3,203 operations on the thyroid gland in St. Mary's Hospital, but one case was observed, and that was doubtful. There was no dependable treatment for tetany. To compensate for glandular deficiency, transplanting parathyroids from other individuals, feeding with animal glands, the use of serum, or the extract of parathyroidal tissue were indicated. To restore the balance in calcium metabolism, calcium salts, acetate or lactate, in four to five per cent. solution should be administered either intravenously, subcutaneously, by stomach, or by rectal enemata. To avoid those factors contributing to the attacks by increasing the toxic metabolic factor, the patient's general condition, especially the gastrointestinal tract, should be given careful attention.

The End Results of Operations in Graves' Disease.—Dr. GEORGE W. CRILE of Cleveland said that in studying the end results of his cases, he had made several generalizations. No patient had died of the disease after leaving the hospital; no patient was made worse by the operation. Every patient was either benefited or cured. Among the factors that influenced the end results were the environment of the patient, the freedom from shock, the means at hand for diversion, as well as the avoidance of strain. The elimination of all nervous shock at the time of operation had proven a good clinical asset. The improvement began usually the next day after the operation and continued for from six months to two years. He regarded patients as cured when they were able to withstand nervous shocks, such as fright, disappointment, worry, etc., in a normal manner. He had found that the time required for a complete cure was dependent upon the environment of the patient. Automobiling, travel, yachting, nature study, a happy turn in the tide of life, were the ideals that facilitated these cures. He knew of no class of patients who were so profoundly grateful, who became such militant partisan advocates of the operative treatment of this disease as the cured cases. There might be hesitation on the part of practitioners to recommend surgical treatment for Graves' disease, but the cured patients shared no such doubt. They were stronger advocates of operation than the most surgical surgeon. The immediate operative risk was approaching that of operations for acute appendicitis. All operative recoveries were either improved or cured. The extent of the cure depended largely on the environment and medical direction during the year following the operation. He knew of no class of patients whose relief was so deeply fundamental as those patients tortured by an ever present pathological emotional state.

Omentopexy in Cirrhosis of the Liver.—Dr. H. H. GRANT of Louisville collected a total of 144 cases from the literature, of which 17, or about 11 per cent., died of the operation; 17, or 11 per cent., were reported as cured; 64, or about 44 per cent., improved, and 32, or 22 per cent., were unimproved. He reported three cases of his own and then drew the following conclusions: 1. That, even in the condition of advanced degeneration of the liver and general toxemia, with resulting ascites, over ten per cent. of symptomatic cures were obtained, and over fifty per cent., at least, were improved, and helped to many months and years of life. 2. That, as this advanced condition was often preceded by a year or more of latency, during which suspicious symptoms had been declared to be the cause, early diagnosis of the lesion would surely lead to the grave unless operation was undertaken; therefore, exploration and repair were justified, with a far better promise than could be hoped for later on. 3. That, as it was not possible to be certain of the character of a cirrhotic lesion before exploration, the surgeon needed not be deterred from the step by any uncertainty as to its applicability, as all forms of cirrhosis were fatal under the expectant plan of treatment.

Primary Sarcoma of the Gall Bladder.—Dr. R. S. CATHCART of Charleston, S. C., said that on June 6, 1908, a case was referred to him for operation with a probable diagnosis of gallstones. The man was forty-five years of age, fairly developed, but had a slight cachectic or septic look. Operation revealed the case to be one of primary sarcoma of the gall-bladder. Its surgical interest was only that the patient was alive and in good health, doubtless due to operation at an early stage.

Dr. RANDOLPH WINSLOW of Baltimore reported a case of congenital gangrene of the right forearm, with successful amputation, in an infant five days old. The points of interest in this case were the early age at which amputation was done and the etiology of the disease. As to the first item, he had not made any search of the literature in order to discover if there were earlier cases of amputation than the one reported, but he was not aware of any. The ability of a frail child of that age to undergo such a mutilating operation, without an anesthetic, was also noteworthy. It was possible that an anesthetic might have been well borne, but he feared to attempt it. As to the etiology of the condition, he was in entire ignorance. He was well aware that intrauterine amputations had been observed, and were attributed to the constriction of the limb by encircling amniotic bands. Sometimes more than one limb was amputated in this manner. Playfair in his "Midwifery," published in 1880, figured a case in which all four limbs had been amputated *in utero*. In the case he had just reported the attending physician specifically stated that no pressure by the cord or by bands was present. There might have been a thrombosis or embolism of the vessels of the arm, but what would have caused such a condition? The gangrene was not of the dry or anemic type, but was more of the obstructive type. The forearm and hand were swollen, discolored, and offensive.

Wherein the Diagnosis of Pellagra Is of Surgical Importance.—Dr. LE GRAND GUERRY of Columbia, S. C., after discussing the digestive disturbances, the pupillary symptoms, the psychic phenomena, and the skin eruptions of pellagra, reported three cases, one of which was sent for operation on account of digestive and intestinal symptoms, but this case was finally diagnosed as pellagra and was not operated on. The patient died several weeks later. Case II was a young, vigorous child, who was taken suddenly ill with an acute abdominal pain, with general abdominal tenderness, and rigidity, but most marked over McBurney's point. The temperature was 102°; pulse, 120. Two pellagra experts saw this case and advised operation. On opening the abdomen the appendix was found slightly inflamed, but entirely inadequate to explain the severity of the constitutional symptoms. Five days later, when the eruptions appeared, the real cause of the trouble was revealed. This case recovered. Case III was a middle aged man who gave a history of chronic abdominal trouble for several years. Although the appendix was removed and the gall-bladder drained, this did not explain the trouble. He was kept in the hospital for a long time under operation, and while there developed a very mild pellagrous rash on the back of his hands, which settled the question of the diagnosis.

Codivilla's Method of Lengthening the Lower Extremity.—Dr. ALBERT H. FREIBERG of Cincinnati said that the fundamental feature of Codivilla's method was the application of the distracting force directly to the skeleton by a rod driven through the os calcis, the elongation being held by a plaster dressing and two steel ferrules. The method differed from Steinmann's, which was proposed later in choosing the os calcis always for the application of force, and in the use of the plaster dressing rather than the weight and pulley. Steinmann's method had a place in the treatment of fresh fractures with unusual shortening or displacement, whereas Codivilla's was proposed for cases in which structural shortening of the soft tissues might be presumed to have taken place. After describing the method and apparatus, as modified for the sake of portability, the author drew the following conclusions: (1) Codivilla's method constituted a valuable addition to our methods of overcoming shortening of the lower extremity. (2) It enabled the surgeon to use great degrees of tractive force painlessly and furnished great ease in handling the patient. (3) It furnished an efficient splint at the site of the break. (4) It was not necessary or even the best method in managing most fresh fractures, even with much shortening. (5) When indicated, it was superior to any method of using adhesive plaster for traction. (6) Used with care, it was free from danger.

The Matas Operation in the Treatment of Traumatic Aneurysm.—Dr. WALTER C. G. KIRSCHNER of St. Louis after reviewing briefly the subject of aneurysm and the principles of the Matas operation, reported four cases of his own of aneurysm of traumatic origin. In the first case the aneurysm resulted from a gun-shot wound of the brachial artery, and was of the fusiform type. Instead of employing obliterative endoaneurysmorrhaphy, after extirpation of the sac, a bi-terminal vein transplantation was performed with a satisfactory result. In the second and third cases large sacciform aneurysms resulted from stab injuries of the brachial artery. The cases were well adapted to the Matas operation, and in each instance good functional use of the extremity was obtained. The fourth case, a sacciform aneurysm of the femoral artery, was interesting on account of the location of the aneurysm below Poupart's ligament, its great size, and the fact that the sac contained a broken knife-blade two inches long. A restorative operation was performed, after preliminary retroperitoneal clamping of the external iliac arteries. The patient made a good recovery. The speaker commended the Matas operation, especially in sacciform aneurysms of traumatic origin.

The Wiring of Inoperable Aneurysms of the Aorta, with Report of Cases.—Dr. J. M. T. FINNEY of Baltimore dealt with the operation of wiring otherwise inoperable aneurysms devised by Moore and modified by Corrado. He dealt with the insertion of from ten to fifteen feet of wire into the interior of an aneurysmal sac through a hollow needle which had been thrust through the aneurysmal wall. After the wire had been inserted an electric current of from ten to fifty milliampères was passed through the aneurysm by attaching the positive pole to the wire and placing the negative pole at the patient's back. After referring to the work which had been done by American surgeons in the development of the technique of this operation, Dr. Finney reported his own list of twenty-three cases treated by this method, including eighteen heretofore unreported. After describing the technique of the operation, which should be carried out with great care, he also referred to the necessity of proper selection of cases for this operation. He called attention to the fact that only aneurysms of the sacculated variety were suitable for this operation. Attention was called to the great value of the fluoroscope in diagnosis of thoracic aneurysms. The risks, both immediate and remote, attending the operation were enumerated. They consisted chiefly in the possibility of the loop of wire sliding along the wall of the aorta and interfering with the action of the heart valves, from emboli or sepsis or charring of the aneurysmal sac with too strong an electric current. Attention was called to the beneficial effects of the operation, which were chiefly the relief of pain and dyspnea and the lessening of pulsation in the aneurysm. These might come on very quickly and afford the patient much relief. The results of the operation, when one considered the conditions one was dealing with, were fairly satisfactory. In a small percentage no benefit was derived. In a large percentage of cases the symptoms were much relieved. In a few death was hastened. Only now and then a case seemed to be cured, but in an otherwise hopeless condition the cure of a single case would render the operation justifiable. Rest after the operation of wiring for a long period was absolutely essential to secure the best results.

Crile's Shock Researches: Clinical Facts Confirming His Conclusions.—Dr. W. P. Carr of Washington, D. C., said that there were three great dangers of surgery, and these were hemorrhage, sepsis, and shock. Ambroise Paré opened the way for preventing hemorrhage, Pasteur, Koch, and others for preventing infection, and now Crile has done the same thing for shock. He had cleared up the mystery surrounding the subject, put shock upon an anatomical basis, and had given it a definite entity. He had discovered the chief causes of preoperative and operative shock and had prevented it in animals. Finally, he had been able to operate upon the most susceptible class of cases in human beings with almost no shock. He had shown that shock was the exhaustion of part of the protoplasm of brain cells, the shrinking of the nucleus and the dissipation of Nissl's granules, from powerful or repeated discharges of nerve impulses, and that these impulses were discharged automatically and involuntarily under the stimulus of afferent impulses received by special peripheral nerve terminals or special sense organs, and transmitted to the brain through afferent nerves. There were no receptors in the brain for such impressand transmitted to the brain through afferent nerves. These afferent impulses causing shock were suggestive of great evil to the organism through previous experiences or through phylogenetic association, and were noxious or noci impulses, causing powerful discharges of brain cells regulating the muscular mechanism of defense or escape from the suggested evil. There were no noci impulses in the brain. These noci associations or suggestions might be conscious or subconscious in character and were not inhibited by chloroform or ether anesthesia. The inhibition of muscular response by the will or by anesthesia did not prevent discharge of the brain cells and the same amount of exhaustion of these cells occurred as if the muscular action of escape or defense were fully carried out. Nitrous oxide anesthesia did prevent shock to a marked extent, however, and was highly recommended for this reason. Cutting the afferent nerves or blocking them with cocaine prevented shock from trauma. Fear was a powerful factor in producing shock. Crile's anoci-association operation was designed to prevent fear and all noci-associations and impulses from reaching the brain, and had been brilliantly successful in practice. The author afforded clinical facts showing that when anoci-association operations were done accidentally there was no shock, and even when the plan was incompletely carried out there was much less shock than similar operations usually caused. He cited high forceps delivery as a typical anoci-association operation because the brain itself had no receptors for noci-associations, and the infant no mechanism sufficiently developed to receive or transmit them, consequently his brain might be compressed, mashed out of shape, even lacerated, without it making a single impulse for defense or escape, and he arrived strong and vigorous and without the slightest shock. All these things strongly tended to confirm the conclusion that Crile's observations had led to, namely, that fear in some form was the chief factor in producing shock, and that the impulses of fear or dread acting upon the brain cells previous to operation were often more potent than the subconscious associations and suggestions during the actual operating.

President's Address: The Cinematograph as an Aid to Medical Education and Research.—Dr. Rudolph Matas of New Orleans stated that as an agent in imparting sanitary and hygienic knowledge of great importance to the masses the cinematograph was playing a most effective part. For instance, in impressing upon the public mind the dangers which lurked about the house fly as a transmitter of disease and of the importance of eradicating this pest, the moving picture was far superior to any lecturer's ability in its power to depict the evil. The picture machine has been applied in France to analyzing the gait of the ataxic, paraplegic, or hemiplegic, and other pathological types of locomotion. Recently Paul Sainton had also made a profitable study of the convulsive ties with moving pictures. With the ordinary cinematograph the photographic film moved discontinuously, being arrested at the moment of each exposure. While this was simple enough at moderate speed, it would be quite impossible when the exposures were made at the rate of two thousand a second, and the mean speed of the film four thousand centimeters a second. These were the figures that were necessary for the study of insect flight, and these were attained on the new instrument. With such a speed, the movement of the film must be continuous and a sharp image was possible only if the exposure did not exceed one million four hundred-thousandth of a second, and for this the electric spark gave a light of sufficiently short duration. In order to study the movement represented on the films, it was merely necessary to pass them through the ordinary cinematograph, making some fifteen exposures a second, instead of the fifteen hundred or two thousand a second employed in the taking of photographs, and then the movements one hundred or more times as slow would be seen and, in many instances, easily followed. Undoubtedly the greatest triumph that had marked the recent advances of the new science of radiocinematography had been obtained by Commandon and Lomon of Paris, who had succeeded in projecting and making perfectly practical the permanent moving reproductions of intensified fluoroscopic images of the skeleton and other organs which thus far had been available only by ocular inspection or by single plate exposures. To show what had been accomplished by the cinematograph in recording surgical operations, Dr. Matas projected upon the screen several of the Doyen films, which he obtained from the Eclipse Company while in Paris this last summer. He regretted that none of the colon films were available, but these would suffice to show what could be done with an ordinary instantaneous film, and he expressed the hope that it would encourage our enterprising teachers and operators in America to adopt this method of recording the most difficult operations. The Edison Company announced that it expected to have very shortly a home kinetoscope which was both a motion picture and stereopticon apparatus, projecting pictures of different sizes. A notable feature of this machine was that it used a film which contained three rows of pictures, which enabled the operator to exhibit on barely eighty feet of film the equivalent of one thousand feet of the regular professional film. As the new film would sell for sixteen cents per foot, making the cost of the eighty-foot film twelve dollars, as against approximately one hundred, or for the equivalent in professional film, one would realize that the cost had been greatly reduced and the kinetoscope made very much more available to the general public. This new instrument would, it was announced, be listed at about fifty dollars, making it comparatively cheap and also available to the individual teacher. The purpose of the company in issuing these new machines and films was to make them especially useful and available for educational work in schools, churches, and all kinds of organizations. By this means the time would rapidly approach when the surgical specialist or teacher of surgery might keep a cinematographic record of his own operations, and thus establish the basis of a mutually cooperative and interchangeable cinematographic surgical clinic in which all the interested workers could participate.

What Can Surgery Do for Gastroenteroptosis?—Dr. Joseph Ransohoff of Cincinnati said (1) that every case of gastroenteroptosis should be studied individually and should not be treated in a routine way, whether by medi-

cine or operation. (2) If, after the removal of a normal or nearly normal appendix, the patient continued to suffer, he should not be lightly classed among the hopeless neurotics. Rather was it the duty of the surgeon to see whether he had not overlooked some visceral displacement or torsion which was the cause of the suffering. A small incision in abdominal work had some disadvantages. (4) The conclusion of the internists, based on laboratory findings, as, for example, after injection of a test meal, could not be made the basis of the functional capacity of the stomach under every-day conditions. (5) In many seemingly hopeless cases of gastroenteroptosis with marked neurasthenic symptoms operation promised relief. If this was the result of suggestion, it was none the less valuable if the relief was permanent. (6) Whereas, of course, internal treatment, abdominal support, and postural treatment should be tried, operative interference should not be unnecessarily delayed, lest the habitus nervosus became too deeply rooted to be eradicated. (7) No gastroptotic patients should be operated on unless some actual functional disturbance could be demonstrated. To relieve this must be the aim of the operation. Given a gastroptosis in which one could demonstrate distinct functional incompetence or deviation, the existence of nervous phenomena did not militate against operation, but might be the chief reason for performing it.

The Essential Factor for the Cure of Hernia in the Male.—Dr. HENRY O. MARCY of Boston spoke of the cure of inguinal hernia by the reconstruction of the inguinal canal to its normal length and obliquity, which was rendered possible only by the use of buried sutures. This method was too well known to require description. It was, of course, dependent upon free dissection, a careful coaptation of the weakened structures posterior to the cord with a firm reconstruction of the inguinal ring; a replacement of the cord, a careful closure of the superficial structures, and sealing of the wound with iodoform collodion without drainage. For many reasons Dr. Marcy thought kangaroo tendon the preferable suture material. His contribution was especially offered as a criticism of a late article published by Lieutenant-Colonel Ruotte of Paris in the *Military Surgeon*, who considered the especial factor for the cure of inguinal hernia to consist of the suturing and resection of the peritoneal sac. Dr. Marcy demonstrated that the special value of Colonel Ruotte's operation must only consist in the closure of the internal ring, which thereby necessarily elevated the cord in its passage through the abdominal structures. Whatever reenforcement might result to the structures posterior to the canal was altogether accidental, and, as a consequence, the so-called French method was unscientific and the results must often be uncertain and unsatisfactory.

Interstitial Ectopic Pregnancy.—Dr. CHARLES R. ROBINS of Richmond, Va., stated that in 1324 cases of ectopic pregnancy collected from the literature by Rosenthal there were less than 3 per cent. of the interstitial variety. The specimen which he presented furnished a very beautiful example and was the only case which had occurred in his own practice. The patient was 27 years of age, colored, threepara, one miscarriage. Her last menstruation occurred in June, since which time there had been no bloody discharge. In the early part of July she was taken with sharp pains in the lower abdomen, worse in the right iliac region. After this for a while she would have a severe attack of abdominal pain at night, felt on both sides and radiating to the shoulder on the right side. She later would have recurring attacks and a few days after an attack could feel a mass in the right side. She was confined to bed for five weeks and then got up for four or five days, when she had another severe attack and was forced to return to bed. Her pains were severe all over the body; she was covered in a cold sweat and had a chill. At this time the pain settled in the right side and had remained there constantly ever since. She had suffered from marked constipation for four months. Urination was frequent and burning. At the time of the examination she had a temperature of 101°. The patient was quite fat, but a tumor could be made out in the lower abdomen half way to the umbilicus. The recti muscles were somewhat rigid, and there was marked tenderness over the right iliac area. On bimanual examination the uterus was made out, although not sharply defined, the enlargement being greater on the right side. The size of the uterus corresponded to about a three months' pregnancy. There was no bloody discharge and the patient said that she had had none since June. A diagnosis of ectopic pregnancy had been made by his associate, Dr. Dorsline, but the possibility of an appendicitis complicating pregnancy was considered. There was a leucocytosis of seventeen thousand, but no differential count was made. On September 7 an exploratory McBurney incision was made and the abdomen found full of fluid blood. A medium incision was then made, the clots cleaned out of the pelvis, and the uterus delivered. The right side was found enlarged with several points of rupture, and with the membranes showing through. The uterus was removed by a supravaginal hysterectomy. Section of the specimen showed an unruptured sac with hemorrhage between the membranes and the walls of the gestation cavity, the chorionic villi well developed, and a perfectly formed embryo. The tube on the right side and the cavity of the uterus were both intact, the latter containing a well developed decidua.

The following papers were also read: "Benign Lesions of the Sigmoid Colon: Ptosis, Mesenteritis; Diverticulitis, and Volvulus: Second Report," by Dr. Joseph C. Bloodgood, Baltimore; "A Plastic Operation for Prolapsus Uteri Without the Necessity for Abdominal Section or for Distortion of Anatomical Relations," by Dr. Barton Cooke Hirst, Philadelphia; "The Principles Underlying the Surgical Treatment of Gastrointestinal Stasis, Due to Causes Other Than Strictural and Ulcerative Conditions," by Dr. R. C. Coffey, Portland, Ore.; "Remarks Upon the Diagnosis and Treatment of Diseases of the Biliary Tract, with Special Reference to the Difficulties and Dangers," by Dr. Maurice H. Richardson, Boston; "Intestinal Obstruction Due to Gallstones with Report of Cases," by Dr. Frank Martin, Baltimore, Md.; "The Limitations of Bone Regeneration and Joint Reconstruction," by Dr. John B. Murphy, Chicago; "Experimental Study of the Arteries in Shock," by Dr. Willard Bartlett, St. Louis; "A Suggestion in Rhinoplasty," by Dr. E. Denegre Martin, New Orleans; "An Artistic and Mathematically Accurate Method of Repairing the Defect in Cases of Harelip," by Dr. James E. Thompson, Galveston, Tex.; "The Fee-Splitting Evil," by Dr. Charles A. L. Reed, Cincinnati; "The Treatment of Vesical and Diverticular Calculus," by Dr. Hugh H. Young, Baltimore; "Treatment of Pyelitis," by Dr. Guy Leroy Hunner, Baltimore; "Additional Cases of Nephroureterectomy," with remarks relative to removal of large suppurating kidneys, by Dr. George H. Noble, Atlanta, Ga.; "Emergency Operation for Cerebellar Tumor Under Artificial Respiration," by Dr. Harvey Cushing, Boston; "A Review of a Series of Operations for All Forms of Appendicitis," by Dr. Edward G. Jones, Atlanta, Ga.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. J. M. T. Finney of Baltimore, Md.; *First Vice-President*, Dr. James E. Thompson of Galveston, Tex.; *Second Vice-President*, Dr. W. P. Carr of Washington, D. C.; *Secretary*, Dr. William D. Haggard of Nashville, Tenn.; *Treasurer*, Dr. William S. Goldsmith of Atlanta, Ga.

Old Point Comfort, Va., was selected as the place for holding the next annual meeting in 1912.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 27, 1911.

THE PRESIDENT, DR. JAMES F. MCKERNON, IN THE CHAIR.

Endorsement of Dr. Doty.—A resolution was voted, on motion of Dr. F. R. Sturgis, disapproving of the manner of investigation of quarantine last summer and protesting against endangering the health of the community by making the quarantine office an object of political reward.

The Relief of Prostatic Obstruction.—DR. J. BENTLY SQUIER read this paper. He said that the question of the method to be used for the relief of prostatic obstruction in each patient resolved itself into a decision between catheter life or operative removal of the prostate. When one considered that catheter life in the hands of the patient carried with it 100 per cent. mortality, and that the average expectation of life after such a method of relief was instituted was about three years, operation was really the conservative procedure when once the necessity of catheter life became the other alternative. The operative mortality would average between 6 and 10 per cent. in unselected cases, while many surgeons had a mortality far below this. To secure completeness of operative cure these patients must be given the benefit of operation early in the course of the disease, and therefore an early recognition of the condition was imperative. Patients often succumbed to the sequelæ of the disease before the primary cause had been appreciated. To emphasize this point Dr. Squier showed a specimen of bladder diverticulum which illustrated the end results inflicted upon the bladder by an unremoved prostatic obstruction. The patient died of suppurative nephritis. The specimen showed an obstructing prostate, multiple diverticula of the bladder, some of which contained calculi, the ravages of chronic inflammation in the bladder wall, dilatation of the ureters, etc. An important fact to be remembered was that the degree of prostatic enlargement might be no indication as to the degree of the urinary obstruction. If, as was the custom with many physicians, reliance was placed on rectal examination to show the presence of prostatic obstruction many cases would remain undiscovered and would be considered ones in which urinary symptoms were secondary to kidney disease or spinal cord lesion. If the time for operation was in the incipiency of the disorder, a large percentage of patients would require operation while they were still sexually vigorous and the question arose as to the effect they might expect the removal of the prostate to have upon the sexual function. The physiology of the prostate in the light of recent research showed that the prostate was a secreting gland and supplied the ingredient of the semen which excited the spermatozoa to motility and made it possible for them to live when in contact with the uterine mucosa. Serralach and Pares, from experimental excision of the prostate in dogs and other animals, had concluded that the prostate and seminal vesicles had similar functions, that one could supplant the other and that either or both of them secreted some substance which rendered the testes active, and that in the absence of these organs the tests ceased to functionate and became small and soft. Walker, in commenting on these results, said that it was most difficult to remove the prostate without taking away the ejaculatory ducts and that in order to justify their conclusions they should have operated upon animals from which the gland could be excised without damage to other structures. Walker removed the prostates from 78 white rats, of which 52 remained fertile and 26 became sterile. He concluded that excision of the vesicles alone, of the prostate alone, or the vesicles and prostate, did not appear to have any effect on the sexual capacity or on the structure and function of the testes. Reports after prostatic removal in men justified them in expecting the power to copulate to remain and in many instances to be improved, with a diminution or absence of the ability to procreate. The possibility of procreation depended upon the patency of the ejaculatory ducts following operation and the ability of the patient to force the seminal fluid out of the urethra during coitus. Dr. Squier said that he mentioned this point because he had a number of patients under observation following prostatic removal who were able to perform coitus successfully, in whom no ejaculation took place during coitus, but who discharged seminal fluid subsequently. In these instances, the support of the prostatic urethra and the resistance of the internal sphincter of the bladder having been removed, the semen would run back into the bladder rather than accumulate in the urethra and be forced out during coitus. The pathological changes which produced prostatic hypertrophy were such as to probably so materially alter, diminish, or stop the secretion of normal prostatic fluid that by the time operation was indicated the semen had already lost this essential element. The patency of the ejaculatory ducts should be preserved during prostatic removal as atrophy of the testes with associated impotence probably took place if the ducts became occluded. The probability of the preservation of the ejaculatory ducts was largely dependent upon the type of operation employed for prostatic removal. Legueu and Papin concluded: 1st, that the ejaculatory ducts in prostatic hypertrophy were always situated behind the enlargement; and 2nd, that after suprapubic removal of the gland they should remain intact. To appreciate this the conception of the prostate as composed of two lobes would have to be given up and replaced by picturing the prostate as divided into four lobes according to the zones of glandular distribution. This view was supported by the embryology of the prostate. The ducts of these various lobes opened into the prostatic urethra posterior to the verumontanum and accounted for the urethra being adherent to the prostate in this situation. The ducts of the anterior lobe emptied into the prostatic urethra on its anterior wall opposite to the verumontanum, the ducts of the posterior and lateral lobes on the sides and floor. The middle lobe lay between the urethra and the ejaculatory ducts, and this lobe was the starting point of prostatic hypertrophy. To better understand the mechanics of urinary obstruction the various lobes of glandular tissue seeming to compose the prostate might be considered as enclosed in a cone the sides of which were formed of dense, unyielding vesicorectal fascia, the apex by the external sphincter muscle, and the base by the internal sphincter muscle. If hypertrophy now took place on one or more of these lobes the cone would contain the enlarged prostate up to a certain point when the hypertrophied glandular tissue would force its way out and follow the line of least resistance. This would be into the bladder through the internal sphincter. The internal sphincter was forced outside the prostate as the enlarging lobe insinuated itself into the bladder between it and the bladder mucous membrane. Remembering that the middle lobe was the commencing point of hypertrophy, it would readily be seen that but little increase in the size of the lobe would effectually close the bladder outlet to the outflow of urine. Assuming that all obstructions to urination occurring in the course of true prostatic hypertrophy were due to the enlargement of the glandular zones which lay between the urethra and ejaculatory ducts and above the verumontanum, they might expect to find the ejaculatory ducts pushed downward by the hypertrophy. As the lobes increased in size a false capsule was produced to the lobes composed of compressed glandular tissue and therefore some prostatic tissue remained unremoved. What was probably accomplished was the removal of an adenoma or fibroadenoma from within the gland. Such being the case, the removal of these hypertrophies should have no

effect upon that secretion which rendered the testes active. This might be explained by its analogy to the ovaries or thyroid. It was therefore reasonable to suppose that, in the event of the removal of the prostate, the function of the testes would remain unimpaired with an absence or diminution of the motility of the spermatozoa. Three factors should be considered when choosing the particular operation to be employed for the relief of prostatic obstruction: 1st, the removal of the obstruction; 2nd, an absolute certainty that the patient would be able to control the bladder and not suffer from postoperative urinary incontinence; 3rd, the preservation of the ejaculatory ducts and sexual capacity. The suprapubic route offered advantages not possessed by the perineal and in addition gave a better opportunity to deal with vesical complications of prostatic obstruction should they be found to exist. There was less danger from a prostatic removal through lateral capsular incision than through median urethral incision; this was the point above all others which should dissuade surgeons from employing the so-called median perineal operation for prostatic removal. If a surgeon had seen a few cases of postoperative urinary incontinence it was difficult to see how he could continue to perform an operation which carried with it so great a chance of such a possibility. In making a choice of operation this factor was almost as important as the rate of mortality. In performing median perineal removal the ejaculatory ducts were regularly damaged; their preservation could be more definitely assured by the suprapubic route.

Dr. WILLY MEYER said the fact that so many papers were still read on prostatic obstruction and drawing large audiences proved that this subject was not lacking in interest. The radical operations upon the prostate had been discussed for fourteen or fifteen years. It was but natural that, due largely to these frequent discussions, the indication for the various operations became more and more refined. It was a pleasure to him to hear Dr. Squier's paper. Dr. Meyer also advised against catheter life as a permissible manner of treatment. But if the patient was opposed to *any* operative interference, he should resort to catheter life. He had seen well-to-do patients who had the leisure to attend to the necessary details exist for many years. In speaking of the pathology of the condition he referred to the work of Tandler and Zuckerhandl of Vienna, and also to what appeared in a recent issue of *Surgery, Gynecology, and Obstetrics*, by Wilson and McGrath, of the Mayo clinic in Rochester, Minn. Regarding operative relief, the Bottini operation and suprapubic and perineal prostatectomy came into consideration. Bottini's operation was here first performed in 1897 by Dr. Meyer and he made it his object to find out by personal experience whether the procedure deserved a place in operative surgery. He did the operation for five years and he found, as he had so long maintained, that if patients were absolutely opposed to operation with the knife, or if there were contraindications, or if the condition of the prostate was carcinomatous, and inoperable radically, these patients should not be relegated to catheter life but have the Bottini operation performed. The result often brought great comfort to the patient and there was such an improvement after the operation that patients were glad it was done. The danger attending this operation was the same as in prostatectomy. With regard to prostatectomy, they had all watched how the pendulum had swung toward the suprapubic route. The latter gave the easiest access to the bladder in case of large calculi, it avoided the possibility of perforation of the rectum, it gave more assurance for the preservation of sexual function; it also was a great aid to the surgeon if he wanted to do the operation in two stages. The two stage operation should be resorted to if the patient was in a septic condition and unable to withstand the one-stage operation. However, to carry a patient through with one operation was an advantage and, in a great many instances, it could be done. Do the radical operation if possible at one sitting! Dr. Meyer reported an interesting case. The patient was a man eighty-two years old who came to him at midnight with a pronounced hematuria and total retention of urine. The two-stage operation, which he advised, was refused and he was compelled to remove the prostate at one sitting. The patient made a wonderful recovery. It was also more humane not to carry the two-stage operation too far. Regarding aftertreatment, he considered it a wise procedure to introduce a catheter through the urethra and leave it in place eight or ten, sometimes twelve, days, with temporary tamponade of the prostatic bed. He had thus seen the suprapubic wound close in twelve days. Carcinoma of the prostate occurred more frequently than was generally supposed. When this condition was met with the entire prostate should, of course, be removed. He believed that the future of this operation would be the complete removal of the gland, the radical operation, but in the sense that surgeons would take no regard for the bladder. Implant the ureters "physiologically" into the sigmoid flexure if the disease had advanced and involved the trigone; treat the tumor then as one would treat carcinoma of other organs. Also give these patients the best chance possible to be cured.

Dr. JOHN F. ERDMANN said he wished to endorse all that Dr. Willy Meyer had stated in regard to the two-stage operation in these cases.

Dr. HOWARD LILIENTHAL wished to emphasize one important point in the technique, the high incision; this would result in a better and a quicker recovery. The method of shelling out the prostate described he had not tried, but he said he would try it because it appealed to him. The tremendously large openings in the bladder should be avoided. It was his practice to take a pair of closed scissors, plunge the points in and then separate the plades, and he thus obtained the opening he wished for. This should, of course, be done carefully and not too rapidly. He called attention to the kind of prostate that would puzzle many, the so-called aberrant prostate, a congenital anomaly; here the prostatic tissue was where it should not be. He told of an instance which was of interest, a friend of his who took longer to urinate than the rest of the boys; he did not have much power in his stream of urine. The boy grew up, married, and was the father of several children. He always took twice as long as anyone else to urinate. He went on a hunting trip and had complete retention of urine, and the catheter was introduced. This was before the days of urotropin. He then came to Dr. Lilienthal for relief. It was soon decided that something should be done and a suprapubic cystotomy was performed to find out what was the trouble. He found only a miserable little projection from the prostate, about as large as a pea, which he removed. He also burned the part with the Bottini instrument. The pathologist reported it to be an aberrant prostate. The patient was completely and permanently cured. He reported a similar case that was now in the hospital. Cancer of the prostate was more common than usually supposed. Whatever else was done they should bear in mind that the first thing was to keep their patients alive; every patient operated upon should have a functional recovery, but they wanted to save life. It was the one hundredth man they were after and not the ninety-ninth who could be saved by the two-stage operation. If necessary do the one-half operation which will give relief; when the time came the patient could be given a little anesthesia and the procedure completed.

Dr. AYRES said he wished to corroborate all that had been said in favor of prostatectomy, but there were certain cases that could be much benefited by treatment. Many men of forty-five to sixty-five years of age with so-called

prostatism with a certain amount of irritation, who were compelled to get up at night to urinate several times, and with general symptoms of irritation from the prostate, could be markedly soothed by massage and the use of the high-frequency current. This would often check the progress of the disease, but would not reduce at all the size of an enlarged prostate. Patients whose business interests would not allow an immediate operation could be rendered quite comfortable over a period of six months to a year. Dr. Ayres said that aftertreatment was very important. Sounds should be passed regularly over a period of three months or more to insure against contracture of the scar at the neck of the bladder. The two-stage operation was a distinct advantage in some cases. He reported a case of a man, 72 years old, with a very bad heart, whose bladder capacity was only two ounces. Under local anesthesia the bladder was opened after twenty-five minutes' work and drainage was established. Four days later the prostate was removed in seven minutes under general anesthesia. The patient recovered, but there is little doubt he would have succumbed had the preliminary operation not been done.

Dr. Raymond C. Coburn said that one thought in mind in these serious operations was the preservation of the patient's life. There were, in these cases, two causes of death which stood out prominently, shock and infection. Dr. Crile of Cleveland had demonstrated that the administration of ether as an anesthetic produced certain pathological changes in the brain cells; that a patient under gas anesthesia suffered only one-fourth the shock that one did under ether anesthesia. Following up the work of Henderson it was found that shock following operations was more often due to the anesthetic administered than to the operation itself. In the class of cases under discussion this was a very important point. Further, the use of ether lowered the patient's resistance against infection; this same effect was reported some time ago by a French investigator as regards cocaine and its derivatives. Again it should be remembered that ether exerted an irritating influence upon the genitourinary tract. They should use nitrous oxide-oxygen and help get these patients well; they then would save that one man out of a hundred.

Dr. Martin W. Ware thought the members of this Society should be very thankful to Dr. Squier for having so clearly pointed out the newer investigations of the French school bearing upon the true nature of prostatic hypertrophy. It was a turning in the lane they had come to in accepting the teaching that the enlargement they encountered was not of the prostate but an hypertrophy of such paraglandular structures lying immediately back of the prostate gland and around the urethral orifice (periurethral). Hence the enlargement was posterior to the ducts. This observation originated in Albarran's clinic, being the work of the pathologists, Motz, Perreanan, and subsequently Cuneo, and was also confirmed by the Vienna school. Clinically there were facts that fitted in with this discovery. Albarran prompted an inquiry as to what per cent. of cases operated upon by him by the perineal route were sterile. The reply was that all but one were afflicted with *impotentia coeundi*. For this reason he mainly abandoned the perineal for the suprapubic route. In the next place, it was a matter of common observation that what corresponded to the dimension and location of a normal prostate was perceptible in the vast majority of cases examined per rectum after much of the tumor mass was removed. Like Dr. Squier, he had for some time effected the enucleation of the gland by introducing the index finger into the introitus vesicæ and with a little pressure readily got into the line of cleavage. As for aftertreatment, he no longer used any irrigation if the tube drained well and only in the later days did he introduce an indwelling catheter in order to help the suprapubic opening to heal rapidly.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 21, 1911.

The President, William K. Polk, in the Chair.

This meeting was held under the auspices of the Section on Orthopedic Surgery.

A Preliminary Report of Bone Transplantation and Osteoplasty in Pott's Disease of the Spine.—Dr. Fred H. Albee read this paper, which was accompanied by a lantern slide demonstration and summarized as follows: (1) It was needless to discuss the inefficiency of all means of ambulatory treatment of dorsal Pott's disease. This was especially emphasized in the tracings of the first four cases, in which the kyphosis continued to increase in spite of all efforts and under the most favorable surroundings, namely; in a well-regulated seaside hospital, where the children were under the constant observation of nurses and surgeons trained in the work, and where they were in the most propitious environment that could be supplied for the cure of tuberculosis. (2) It had become a well-recognized fact that whenever bone fixation of a tuberculous joint occurred the tuberculous process immediately subsided. Now as the physiology and pathology of bone tissue were the same wherever it was they were justified in expecting that if they got the same bone fixation in the spine the effect would be the same. This was best accomplished by a firm cortical bone graft with union to the vertebræ involved and the healthy ones on either side, which assured not only the prevention of further deformity in two mechanical ways, as stated (leverage and splint action), but should also cause the disappearance of the tuberculous process. The leverage action arose from the two lateral facets, acting as a broad fulcrum in the case of each vertebra, and the bone graft furnished a means of holding the long arms of the levers or the spinous processes together, thus separating or preventing the crushing of the tuberculous vertebral bodies. It should be noted that the nearer this bridge of bone was to the tips of the processes the greater the leverage. The spinous processes were split as near the center as possible, and in such a way as not to result in a green-stick fracture of the larger portion; therefore, the recent objection that the operation was asymmetrical did not hold. (3) The above described bone-grafting procedure was believed to be preferable to any in which breaking or cutting of the spinous processes destroyed entirely (or until union took place) the natural as well as the acquired support and leverage of the spinous processes. Again, it furnished a continuous bridge of bone spanning the entire number of vertebræ which it was desired to immobilize, and therefore should be under Wolff's law, and should become stronger by the influence of undue stress or motion, which bent it. Or, in other words, it was an imitation of nature's success, as had been pointed out by Brackett, whereas it had been feared that these same conditions of motion would prevent bony union, and favor a fibrous union or pseudoarthrosis in the case described as osteoplasty. (4) If bone union of graft to spinous process should not occur the same mechanical effect of leverage in a large degree would still be obtained from the union of the embodied bone splint to the surrounding dense ligamentous structures at the tips of the spinous processes as well as the splint support. (5) Perfect immobilization and support of the few involved vertebræ in the respiratory area of the spine were secured, which was an impossibility by any external mechanical device or treatment. The recumbent treatment on a Bradford frame was not excepted on account of the constant respiratory movement of the ribs and attached vertebræ. (6) Fortunately on account of the anatomy of the part it was not necessary to enter the focus of the disease; therefore, primary union of the

soft tissues with immediate bone union could be expected. (7) The normal supports of the spine were not interfered with, as the ligaments and muscles were not cut or separated from the vertebræ. (8) The operation was by no means a formidable one. The technique was very simple, in one case the total operating time was but fifteen minutes. (9) When possible a recession of a kyphosis by a long recumbency on a reversely bent Bradford frame should be secured. This method offered great promise of holding the correction obtained; whereas, without this artificial support there was a great tendency of a relapse when ambulatory treatment was resumed on account of the inhibition by the tubercle bacilli of the new formation of bone. (10) A bone graft was far superior to an internal metal splint because, by following Wolff's law, it would become thicker and stronger if necessary to hold weight or strain brought to bear on it; whereas no dependence could be placed on an internal metal splint, suture, or screw, applied to the bone, to hold continued weight or strain because of the bone atrophy and absorption which took place directly around the metal. This occurred when no strain was present. Silver wire and screws, which had been placed through bone only a few months before, had been found in the soft tissues where they had fallen through or out of the bone without being influenced by strain. For this reason and because of the ever-present danger of sepsis about buried metal, it would seem that bone grafting would prove preferable to the internal metal splint of Lane.

Operation for Progressive Spinal Deformities.—Dr. Russell A. Hibbs read this paper and illustrated it by lantern slides. He said that operative measures for attacking the disease in the vertebræ directly had not been successful; neither had specific treatment for the tuberculous process proper given much help. The only method which had proved to be of distinct value was that of securing rest of the diseased joint by immobilization, and in those regions of the spine where the most perfect immobilization could be secured the best results were obtained in the shortest time and with the least amount of deformity. The writer some years ago perfected a method of treating the knee joint by removing the patella from its periosteum and mortising it into the joint after a space was freshened to receive it. The periosteum was then stitched above to the periosteum of the femur, and below to that of the tibia. In these cases the patella bridged the space between the two bones and the periosteum produced new bone sufficient to make a bony bridge between the two bones, and to secure a safe bony ankylosis. This operation led to the conception of the procedure applied to Pott's disease. After experimenting for a time on the cadaver he was encouraged to attempt the operation on a living subject. His first patient was a boy nine years of age who entered the Orthopedic Hospital with a lumbar Pott's disease and a moderate kyphosis involving the last dorsal and the four upper lumbar vertebræ. He was admitted to the ward because of the activity of his disease as evidenced by the characteristic protective gait, abdominal pain, etc. He was selected for operation because his disease was in a region where it would be possible to secure good *x*-ray pictures, which would demonstrate whether or not the bridge was produced. An incision was made in the median line of the back from the twelfth dorsal to the last lumbar vertebra and down to the tips of the spinous processes; the ligament was divided longitudinally in the center, and the periosteum split over the tips of the spinous processes and over their upper and lower borders. It was stripped down to their base and from the lamina to the articulation of the neural arches. The last dorsal and three upper lumbar spinous processes were thus denuded. The periosteum was removed and retracted with great care so as not to tear or puncture it. Then the respective spinous processes were fractured by means of a small chisel, as close to their bases as possible, without opening the canal. These processes were then placed so that the base of the process removed made contact with the base from which it was removed, and its tip was placed in contact with the base of the next spinous process removed below it. In like manner they were all so placed as to form a continuous bone bridge. The reflected periosteum was brought together laterally and in the median line over the processes with a continuous catgut suture, reinforced by three interrupted silk sutures. The skin wound was closed with silk. The wound was dressed and a plaster dressing applied from the knees to the axilla with the spine in a position of slight overextension. During the first forty-eight hours the patient suffered a great deal of pain and it was impossible to relieve it. Two weeks later the plaster was removed and a brace applied with the uprights separated so that it would not press on the wound. In all other cases braces had been applied instead of plaster. On the tenth day the wound was perfectly healed. Four months after the operation *x*-ray pictures were taken which demonstrated unmistakably that the bone bridge had been formed and was of considerable size and strength; the braces were then removed. Since that time the boy had lived an unrestrained life and there seemed to be an absolute obliteration of motion over the operative field. He had had no symptoms of disease since the operation and no increase of deformity up to the present time, eleven months after the operation. Since that time twenty patients had been operated on at the Orthopedic Hospital, ranging in age from four to twenty-five years. Two had the disease in the lumbar region, eleven in the dorsolumbar, and eight in the dorsal. Three of them had discharging sinuses and four had abscesses which had not been opened. In none of these patients had there been the slightest reaction from the operation, or any complication whatever. No attempt had been made to correct the deformity in these patients by means of force. The exercise of force under an anesthetic in the correction of deformity in Pott's disease was unwise. In all of the cases the deformity had been considerably diminished by this operation. Ten of the patients had been without support for periods ranging from three to twelve months, and none of them had shown any increase of the kyphosis or any other symptoms which would suggest that there was not sufficient support over the diseased area. In determining in a given case the number of vertebræ to be fused, Dr. Hibbs had been guided in most instances by the kyphosis, by *x*-ray pictures, and, in cases without deformity, by the extent of the rigidity of the spine. He had always been careful to make the brace sufficiently long, even making it longer than seemed necessary. The stiffening of a small segment of the spine did not seem a serious matter in view of the fact that the remaining healthy joints would compensate for the loss of function in a few. With regard to the question of age, it had been thought at first that it was doubtful if under the fifth or sixth year it would be possible to produce such a bone bridge, but he had done this successfully in a child of four years. While it was impossible at this time to reach final conclusions as to the value of this operation, it might be fairly stated that it was an operation which subjected the patient to very small risks and that it complicated in no way the application of ordinary methods of treatment. It also seemed to be proved that a fusion of the posterior aspect of the vertebræ did take place and that the bridge might be produced, as had been shown in a sufficient number of *x*-ray pictures. The operation should be done before deformity occurred in any region of the spine where the disease existed.

Dr. Eugene Wilson Caldwell presented a plate that had

been taken by the late Dr. A. M. Phelps in 1896, showing an ununited fracture of the radius. The plate, however, was a poor one, judging by present-day standards.

Dr. CHARLES F. PAINTER of Boston, Mass., said he had had very little experience in bone grafting, and what he wished to say regarding the subject was in a general way. They all knew of the enthusiasm with which this subject was taken up. Only a few years ago in France there was advocated the forcible correction of the spine; then men in America followed out this forcible correction of the spine and recorded failures. In the same way osteoplasty had a limited field. It was only a short time ago that everybody undertook to treat and cure neurasthenia by suturing kidneys, operating for enteroptosis, or some other ptosis, but eventually it was noted that these were not the proper procedures for the cure of neurasthenia. Now there had been a revival of interest in this subject but men had been trying to explain these functional disturbances of the nervous system as an autointoxication, the result of some visceral ptosis. He said it was rather interesting, and yet provoking, when one approached the subject of bone grafting, and when one looked over the subject in the literature, to learn for what purposes it had been resorted to, for defects in bone, the result of congenital disturbances, pathological defects of osteomyelitis, replacement of bone that had been destroyed as the result of malignant disease, or destroyed as the result of Pott's disease, and so on; all these conditions had been sought to be remedied by osteoplasty. Some of these procedures appealed to them and some did not. He thought it was time to orient oneself and not to get too enthusiastic about osteoplasty. One should carefully inquire whether or not it was feasible to resort to osteoplasty in any given case. There was no doubt in his mind that when the technique was perfected everything that was transplanted would stay. Yet they should at present consider if eventually the results were going to be better, or whether the patients operated upon would be well off, or not so well off afterward. The experimental stage of this procedure was, of course, necessary. This was not a new procedure and it had a definite field in properly selected cases. Experimentally it had been proven that transplanted bone did not remain as such very long. It seemed to him that they should approach the subject of oseoplasty in a reasonable frame of mind; there was no doubt but that they could secure good results in a restricted class of cases. Dr. Painter said he had had experience in osteoplasty in two cases only, both young children, three and a half and four years of age, respectively. Dr. Albee's method was used. The grafts evidently were going to stay just where they were placed. The question arose, however, would any growth of the graft keep pace with the growth of these children; was there going to result an opisthotonos? It had been shown that such grafts did not grow very much in length when transplanted, although some believed that they did grow to some extent.

Dr. HOWARD LILIENTHAL said a few words from the standpoint of the surgeon, and not from that of the orthopedist. First regarding the feasibility of this procedure for purposes of immobilizing the spine, while listening to the papers he had no doubt in his mind but that the ordinary stiffening of the spine by surgical operations was an advance over all other methods of treatment. They all knew that an unmixed tuberculosis was not a malignant infection and that with absolute rest, building up the patient's resistance, the condition would gradually subside, calcification take place, and a practical cure follow. This was so with tuberculosis anywhere in the body. Of course, if there was a mixed infection, where there was a tuberculous infection with another infection present on top of it, that was another question. But these spinal cases seemed to be a pure tuberculous infection and not a mixed infection. Under the employment of proper hygienic measures, combined with absolute rest, the results had shown that possibly the disease was a curable one. The question then came up, how should this rest be obtained? Anyone who had looked at a fracture of a bone through the window in the splint must be struck by the fact that there was motion between the fragments. It was because of this that Lane of London had devised his method of bone plating, and had given them an enormous advance over the old-fashioned methods of treating fractures. The bone plate method was one that now had come to stay. When it came to the question of bone immobilization it then came to the question of operating upon the bone itself. Dr. Lilienthal thought that this disease would becomes more or less an operative one, and he believed in the employment of apparatus, but at the right time.

Dr. T. HALSTED MEYERS said that the cure of tuberculosis was effected by surrounding the tuberculous area with new connective tissue. He wished to emphasize the point made by Dr. Hibbs that too much force should not be exerted in correcting those deformities which already existed; of course, such deformities might be diminished by cutting off parts of the spines. What interested him very much was the statement made regarding the operative procedure wherein the periosteum was removed; the periosteum should be left whenever possible, for it served to aid in the increase of bone and, therefore, an increase in the solidity of the parts. Many of these deformities should be reduced as much as possible before operation was resorted to. The procedure appealed to him.

Dr. HENRY LING-TAYLOR said he had had the opportunity of observing Dr. Albee's work in this class of cases and he wished to confirm the statement made that the operation itself was not a formidable one, nor was it a long one. The operative results were very good. The treatment of diseases of the spine had not improved a bit in thirty years; the treatment as practised now in this country was essentially the treatment of Davis, Sayre, C. F. Taylor, and others, based on immobilization, fresh air, long-continued rest in bed, with counterirritation by setons, and so forth. During thirty years they had seen arise two or three so-called panaceas. One was the tuberculin test, which practically was of no use in Pott's disease of the spine; another was the forcible correction of the deformity, which was also without effect. However, in spite of these carefully devised operations, practical gains had not resulted in the management of their cases.

Dr. H. J. BOGARDUS said that the operation of Dr. Hibbs was sufficient to produce the effects desired and without the introduction of bone or other foreign material. The periosteum should be preserved; there should be a complete building up of the sheath of the periosteum throughout the length of the diseased process. This was, in his opinion, the keynote of the success of the operation. When the operation was first suggested by Dr. Hibbs more than a year ago he was fearful that, because of its close proximity to the active bone tuberculosis, the resulting traumatism might light up a more virulent type of the disease, but this had not so far occurred. The reverse seemed to be true. The operation seemed to act as a stimulus to Nature's reparative process. It seemed to him that they had made a long stride in advance in solving the difficulties which accompanied the serious problems confronting them.

Dr. A. JACOBI said he was pleased with the historical review that Dr. Painter had given them because it showed that methods used in the past were such that there was left much to be desired. Bone tuberculosis of the spine was confined to the bodies and not to the arches and processes. The process in the bodies would result finally in fearful abscesses which generally killed the patients. He

could not imagine any operation which would do more than steady the spinal column. He wished to congratulate the gentlemen who had suggested an operation which pointed to the accomplishment of such a result, but he feared there would be ill successes. When operations were done they did not reach the seat of the tuberculous process at all, and could not possibly do so. Dr. Jacobi said he had treated many cases of tuberculosis of the spinal column, and particularly of the small bones of the hands and feet, and a large number of these cases had died. They had been told that in thirty years there had been no gain in the treatment of these cases, and he was almost of the same opinion. They needed, however, in the treatment of this disease not only the hygienic treatment but internal constitutional treatment. He had not treated bone disease, or inflammatory disease of bones, or other diseases of bones without using phosphorus internally, phosphorus and not phosphates. He recommended it early in rickets. He said he had given phosphorus (not the phosphates) internally in cases of tuberculosis of small bones for many years as a routine measure. Again there was no better bone builder than arsenic, and this was a metal he gave in every case of bone tuberculosis, the same as he gave it in all other forms of tuberculosis. If they combined this internal treatment with their surgical treatment there would result, in his opinion, many successes, and they would do better.

Dr. JOHN JOSEPH NUTT said that three years ago he experimented on eight dogs in the laboratory, attempting to immobilize the spines by transplantation of parts of ribs; these pieces were placed in the angle between the processes and the bases of the spine. All the work was done in the dorsal region, and none of them became ankylosed. He did not believé they could by any operation immobilize the dorsal vertebræ; the respiratory movements had much to do in its prevention.

Dr. FRED H. ALBEE said that Dr. Nutt's cases were normal ones and should not be compared with those that were diseased. He emphasized the importance of certain features of his operation, and among these were shortness of time in operating and the fixation of the spine by the bone splint. He called attention to the large number of *x*-ray pictures taken for Dr. John B. Murphy of Chicago of bone grafts, a large number of cases taken for a large number of purposes. He called attention to one in particular where one-third of the upper part of the humerus had been bone grafted, and the pictures taken showed the rapid development of the bone which supported the upper arm.

PHILADELPHIA NEUROLOGICAL SOCIETY.

AT a stated meeting held December 22 Dr. GEORGE E. PRICE reported "A Case of Spastic Paraplegia, Presenting Loss of the Senses of Pain and Temperature on the Entire Right Side, with Ataxia and Increased Reflexes." The patient was a man, 37 years old, with a history of gonorrhea, syphilis, and alcoholic excess, who had been subjected to several operations on the left mastoid bone for the relief of an aural discharge. The symptoms were attributed to multiple syphilitic lesions. Dr. CHARLES K. MILLS made a preliminary report on "A Case of Ataxia of the Left Upper Extremity, with Paralysis of Emotional Expression on the Right and Loss of the Senses of Pain, Heat, and Cold on the Entire Right Side." On post-mortem examination evidences were found of interference with the cerebellar blood supply on the right side. Dr. THEODORE H. WEISENBURG exhibited a series of moving pictures illustrating athetoid movements in cases of spastic diplegia, the tremor and gait of paralysis agitans, the incoordination of multiple cerebrospinal sclerosis, and the peculiar motor anomaly observed in the case of Dr. Mills. Dr. J. W. MCCONNELL demonstrated "A Case of Muscular Dystrophy." The patient was a man, 38 years old, who was not known to have presented any abnormality up to the age of four years, when he fell from a third story window. Thereafter there developed weakness and wasting of the thighs and buttocks, with a peculiar waddling gait. The knee-jerks were preserved though enfeebled, as were also the electrical reactions though with qualitative diminution, but not with qualitative change. There was no fibrillary contraction, and sensibility was unaltered. The calves were not enlarged or indurated, and the scapulæ were not flaring. The patient climbed up his lower extremities in rising from the floor. Dr. CHARLES K. MILLS reported an instance of "Thumb-clonus in a case of Hemiplegia and Hemianesthesia." Dr. FRANCIS X. DERCUM presented "A Case of Adiposis Dolorosa with Joint Changes." The patient was a woman who, in addition to painful masses of fat about the arms and thighs, presented tenderness and want of mobility of the knee joints presumably due to deposition of fat. Dr. Dercum presented also a woman who exhibited multiple painful lipomata, and he considered this case likewise one of adiposis dolorosa. Dr. H. MAXWELL LANGDON presented a communication entitled "Report of a Case of Acute Encephalitis Superior of Wernicke." The patient was a man who in the sequence of an attack of influenza exhibited difficulty in the use of the lips, interference with the actions of the muscles of the eyes, and impairment of vision. Improvement to the point of practical recovery ensued under treatment with mercurials, sweats, and other forms of derivation.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

AT a stated meeting held January 3 Dr. JAMES TYSON read "A Memoir of the Late Dr. A. O. J. Kelly." Drs. GEORGE W. NORRIS and GEORGE FETTEROLF presented a communication entitled "The Anatomical Explanation of the Relatively High-Pitched and Less Resonant Percussion-Note Normally Found at the Right Pulmonary Apex." A study of frozen sections showed that the apex of the right lung is rather conical in shape, while that of the left lung is somewhat dome-shaped; also that the trachea lies in close proximity to the apex of the right lung anteriorly, while the descending aorta occupies a similar position posteriorly on the left; further, that the innominate, with its divisions, the right subclavian and the right carotid, is in more intimate relation with the right apex than are corresponding vessels on the left side with the left apex. The conditions described were found equally in left-handed and right-handed persons, and control examination of left-handed individuals showed that the physical signs are in general identical with those in right-handed persons.

Expressions of regret on the untimely death of Dr. Arthur V. Meigs, a former president of the college, were made by the president, Dr. G. E. de Schweinitz, by Dr. S. Weir Mitchell, and by the vice-president, Dr. J. C. Wilson. On behalf of the donors, Dr. A. P. C. Ashhurst and Mr. John Ashhurst, Dr. Richard H. Harte presented a portrait of the late Dr. John Ashhurst, Jr., a former president of the college. Dr. Hare read an account of Dr. Ashhurst's literary activity.

Announcement was made that Mr. Eckley B. Coxe, Jr., had proffered the ground rent on the lot to the south of the college building, on condition that it be reserved as a memorial to the late Dr. Wharton Sinkler. The lot itself had already been presented by the donor.

The annual election for officers resulted as follows: *President*, Dr. G. E. de Schweinitz (reelected); *Vice-President*, Dr. J. C. Wilson (reelected); *Secretary*, Dr. Thomas R. Neilson (reelected); *Treasurer*, Dr. Richard H. Harte (reelected); *Honorary Librarian*, Dr. Frederick P. Henry (reelected).

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. By Dr. L. KATZ, H. PREYSING, and F. BLUMENFELD. 382 pages; paper; price 3 M. Curt Kabitzsch, Publisher, Wurzburg.

OM MEDFODT HALSFISTLER OG ENDEL MED DISSE BESLEGTEDE ANOMALIER. By FRITHJOF LEEGAARD. 147 pages; illustrated; paper. Steen'ske Bogtrykkeri, Publisher, Kristiania.

ÄRZTLICHE STANDESPFLICHTEN UND STANDESFRAGEN. By DR. L. FISCHER. 189 pages; paper; price 4 M. Wilhelm Braumuller, Publisher, Leipzig.

TEXTBOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By JOHN J. REESE, M.D. Eighth Edition. Revised by D. J. McCARTHY, A.B., M.D. 660 pages; cloth; price $3.00 net. P. Blakiston's Son & Co., Publishers, Philadelphia.

CLINICAL DIAGNOSIS. By JAMES CAMPBELL TODD, Ph.B., M.D. Second Edition. 460 pages; illustrated; cloth; price $2.25 net. W. B. Saunders Company, Publishers, Philadelphia.

DISEASES OF THE SKIN AND THE ERUPTIVE FEVERS. Second Edition, Revised. By JAY FRANK SCHAMBERG, M.D. 573 pages; with 235 illustrations; cloth; price $3.00 net. W. B. Saunders Company, Publishers, Philadelphia.

PHYSICAL DIAGNOSIS. Second Edition, Revised. By JOHN C. DACOSTA, JR., M.D. 557 pages; with 225 original illustrations; cloth; price $3.50 net. W. B. Saunders Company, Publishers, Philadelphia.

FOURTH REPORT OF THE WELLCOME TROPICAL RESEARCH LABORATORIES AT THE GORDON MEMORIAL COLLEGE, KHARTOUM, with Prospectus. Vol. A-Medical. ANDREW BALFOUR, M.D., Director. 404 pages; illustrated; cloth; price $5.00 net. Toga Publishing Co., Publishers, New York.

RETINOSCOPY. By JAMES THORINGTON, A.M., M.D. Sixth Edition. Revised and Enlarged. 71 pages; illustrated; cloth; price $1.00 net. P. Blakiston's Son & Company, Publishers, Philadelphia.

PROCEEDINGS OF FIRST ANNUAL MEETING OF THE MEDICAL SECTION OF THE AMERICAN LIFE CONVENTION. Held in the City of Pittsburgh, Pa., September 20, 1911. 110 pages; paper.

FURTHER RESEARCHES INTO INDUCED CELL-REPRODUCTION AND CANCER. By H. C. ROSS. 63 pages; illustrated; cloth; price $1.00 net. P. Blakiston's Son & Co., Publishers, Philadelphia.

REPORT OF THE SURGEON-GENERAL U. S. ARMY TO THE SECRETARY OF WAR. 1911. 253 pages; illustrated; paper. Annual Reports, War Department, Publishers.

PROGRESSIVE MEDICINE. By HOBART AMORY HARE, M.D., and LEIGHTON F. APPLEMAN, M.D. Vol. IV. 326 pages; illustrated; paper; price $0.00 per annum. Lea & Febiger, Publishers, Philadelphia and New York.

MANUAL OF OPERATIVE SURGERY. Fifth Edition. By JOHN FAIRBAIRN BINNIE, A.M., C.M. 1,153 pages; with 1,365 illustrations; cloth; price $7.00. P. Blakiston's Son & Co., Publishers, Philadelphia.

FORTY-SECOND ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF MASSACHUSETTS. 630 pages; cloth. Wright & Potter Ptg. Co., Publishers, Boston.

MODERN SURGERY. By JOHN CHALMERS DA COSTA, M.D. Sixth Edition. 1,502 pages; with 960 illustrations; paper. W. B. Saunders Company, Publishers, Philadelphia.

HEREDITY IN RELATION TO EUGENICS. By CHAS. B. DAVENPORT. 208 pages; with 175 illustrations; cloth; price $2.00 net. Henry Holt & Co., Publishers, New York.

NEPHRITIS. By Dr. MARTIN H. FISCHER. 203 pages; illustrated; cloth; price $2.50 net. John Wiley & Sons, Publishers, New York.

THE CONTROL AND ERADICATION OF TUBERCULOSIS. By H. G. SUTHERLAND, M.D. 451 pages; illustrated; cloth. William Green & Sons, Publishers, Edinburgh and London.

A REPORT ON HEMOGLOBINURIC FEVER IN THE CANAL ZONE. By W. E. DEEKS, M.A., M.D., and W. M. JAMES, M.D. 177 pages; paper. Isthmian Canal Commission, Publishers.

SOZIALE PATHOLOGIE. By DR. ALFRED GROTJAHN. 601 pages; paper; price 18 M. August Hirschwald, Publisher, Berlin.

INTERNATIONAL CLINICS. Vol. IV. 21st Series. By HENRY W. CATTELL, A.M., M.D. 322 pages; cloth; price $2.00. J. B. Lippincott Company, Publishers, Philadelphia.

Medical Items.

Treatment of Acute Suppurative Peritonitis.—Marquis and Lafon report a mortality of only 30 per cent in 158 cases treated according to Murphy's method.—*Archives Générales de Chirurgie.*

Treatment of Cardiopathies.—Nobecourt says that in the presence of arrhythmia in a child one must not at once think of giving heart stimulants, but should seek out the cause of the arrhythmia, which may be due to changes in metabolism. Arrhythmia and tachycardia may be due not to heart disease but to nervous, orthostatic, or functional causes. They may result from anemia, dilatation of the stomach, constipation or diarrhea. If these troubles are first attended to one will find it unnecessary to give digitalis. There are true physiological arrhythmias occasioned by modifications of respiratory rhythm and nervous influences. Alimentary hygiene, hydrotherapeutic measures, physical treatment, and massage will relieve all of these troubles. All the infectious diseases affect the rhythm of the heart, and this is not always due to a true myocarditis. Applications of ice over the heart act as a tonic to the cardiac muscle. Subcutaneous injections of strychnine and sparteine are useful at the same time. The infectious diseases also cause a nephritis which brings about heart lesions. In cases of mitral insufficiency, as long as compensation is good, medication is useless, even harmful. Exercises should be neither too severe nor too slight. Rapid asystole may result from gastric troubles. Repeated acute attacks of rheumatism cause cardiopathies. Here respiratory gymnastics and graduated exercises of the arms and legs are valuable.—*Annales de Médecine et Chirurgie Infantiles.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended January 12, 1912.

SEXUAL DISORDERS IN THE MALE CLINICALLY CONSIDERED.*

By EUGENE FULLER, M.D.,

NEW YORK.

LOOKING back to the time when I was a medical student, an incident occurred which impressed me considerably. As a feature of the curriculum, I was assigned to a clinic, a part of my duty being to take the clinical history of a patient previous to his coming before the instructor for his diagnosis and comments. In the course of this work a man was assigned me whose chief symptoms were of a sexual nature. The man struck me as a severe sufferer. After noting carefully his symptoms, I brought the case before the instructor and commenced to detail my clinical notes. Hardly had I begun to do this, and as soon as it became evident that the case related to a sexual disorder, the instructor frowned upon the patient, gave him a sharp reprimand for allowing his mind to dwell on the subject, and waved him aside and out. My confidence in the instructor was shaken. I thought him ignorant as far as that patient's condition was concerned, as well as narrow minded. Further experience, however, showed me that this particular instructor had handled the case in what was then considered the approved, stereotyped manner. As far as I could see the only apparently congenial surroundings for sufferers of this class seeking medical advice were furnished by quacks or, at best, by off-color members of the profession. Conditions existing in those days have not changed much, as far as the rank and file of the profession is concerned, in this particular branch of medicine. One sees this often in the course of clinical lectures bearing on this subject. When questions relating to the sexual function are being asked of a patient, many in the audience laugh or snicker, while others await seemingly in the expectation that the professor has some lewd joke or purpose in mind as a reason for making such inquiries.

Genitourinary surgery is at present a well recognized department of medicine, and has assigned to it numerous skilled workers. Still, if one studies the work now being accomplished in this department, he will find that 95 per cent. of it is devoted to the urinary portion of this combined field of medicine, the genital end being largely ignored. So palpable is this discrepancy that I have often been led to remark in the course of my clinical teaching that genitourinary specialist is a wrong and misleading term when applied to many, the substitute term urinary specialist being really the proper one. As an illustration of this, some time ago I received an English cable from a patient of mine, asking me to cable back the name of a London specialist, which I did. This patient had an old seminal vesiculitis, which required from time to time some treatment to keep him comfortable. The patient has now returned, having been wholly unrelieved of the relapsing symptoms due to his seminal vesiculitis. I found the London authority had never questioned the patient at all regarding his sexual status and had never made a digital examination per rectum, but had explored most carefully the urethra, bladder, and kidneys, had found them in order, and had then simply expressed surprise at the persisting symptoms, which he stated he was wholly unable to account for. It is a queer and interesting matter of record that the American Urological Association, in its articles of incorporation, expressly prohibited the consideration or discussion of all genital or sexual topics in its proceedings. My attention was first called to this several years ago, when its secretary regretfully declined to receive a paper, which I offered to read before an annual meeting, because it bore on the forbidden topic. I am glad to say this curious restriction has recently been eliminated.

Now that so many neurasthenic, mental, and rheumatic conditions, formerly wholly dissociated in the popular as well as in the professional mind with sexual disorders, have been found to be dependent on lesions of the seminal vesicles, any lurking hesitancy against a study of the subject from reasons of prudishness ought to disappear.

In diagnosticating a genitourinary case, it is well to have some definite system, without which there is always special danger of error. The routine I follow in this connection is (1) the voluntary recital by the patient of his clinical symptoms, (2) the putting of questions to the patient bearing on the urinary function, (3) the putting of questions bearing on the sexual function, (4) questions relating to general physical and mental conditions, and among these are included those relating to family history. After this come the physical and special examination. The order here observed is (1) an external inspection and general examination, (2) observation of the act of urination and of the first portion of urine voided, (3) digital palpation per rectum of the prostate, seminal vesicles, and vesical floor, followed by the voidance of the remaining portion of the urine, (4) urethral examination and examination, if required, of the upper urinary tract. In carrying out this régime, the genital and the urinary conditions are equally and impartially considered.

I often find the clinical histories of my hospital cases very deficient as regards the sexual status, and, on calling the attention of the house staff to the fact, discover that, never having received any medical instruction on the subject in their undergraduate course, they really do not know the normal from the abnormal, and so are not able to ask intelligent questions bearing on the subject.

*Read before the New York Society of the American Urological Association, December 6, 1911.

Although I cannot in this short paper go fully into this particular, still a little should be said in the way of illustration. Suppose, for instance, a man reports, complaining of impotency. The clinical history as regards prognosis is of the greatest moment. If the clinical history shows that the impotency is an acquired condition, potency having previously existed, a very important fact is recorded. The fact that the normal function previously existed of itself rules out diagnostically the presence of numerous conditions. In arrested or nondevelopment of the sexual organs, in certain neurotic states, and in connection with primary mental defects, there would be no history of a lost function, the impotency being a primary condition. If the impotency is found to be an acquired condition many questions should be asked, the answers to which will aid not only in making an exact differential diagnosis but also and especially in determining the etiology and prognosis. If there has been self-abuse, the age at which it was initiated, the period covered by it, the frequency of its indulgence, and the nervous or reactive symptoms, if any coexisting, should be determined. The age at which sexual intercourse was initiated and the frequency of its practice subsequently should be asked. If intercourse was commenced at an early age, it should be determined whether a matured woman played the part of seducer or whether the act was practised with girls of a corresponding age. The importance of this point lies in the fact that a matured woman so getting control of a boy is usually of the nymphomaniac type, who so taxes the undeveloped organs of the boy as to frequently implant thereon crippling lesions of a very severe grade. If gonorrhea has existed, the patient's age at the time of the first attack should be noted, as well as the number and dates of subsequent attacks, together with the clinical history of the attacks, especially as to involvement of the epididymes and as to the coexistence of symptoms of sexual excitation such as priapisms, exacerbation of sexual desire, and painful or disturbing emissions. The comparison of the sexual function subsequent to gonorrhea with that previously existing should be determined. If none of the preceding factors are found to have existed, and a perfectly exemplary life void of all coitus has apparently been led in a man approaching middle age and unmarried, questions are apt to reveal the fact that for years, probably well up toward thirty, strong and apparently natural sexual desires existed, which through the exertion of a strong will, aided by moral convictions, he was able to suppress and control. Then followed a period in which control was an easy matter, the erections becoming few and feeble. Finally, around forty, the question of marriage being entertained, it was found that erections no longer occurred under normally exciting conditions and that the desire had fled. In another case, closely resembling the preceding one but in which more disturbing mental and nervous factors are usually present, there will be in the early history a record of much sexual teasing through caressing and fondling amorously inclined women, such actions not being associated with sexual intercourse. In this latter class it is unusual not to find a coexisting history of artificial relief through masturbation. In another class, the majority of these being married men, there will, before the time of the existing impotency, be a history of a long period, during which the sexual act had been practised in an irregular manner in order to avoid conception, the object being to withdraw the penis just previous to ejaculation. In getting the history of such sufferers, it will usually be found that for a period previous to the development of sexual weakness, there was one in which there seemed to be an unusual degree of strength, there being at that time developed a great ability to prolong unduly the period of coitus before the sensation of impending ejaculation became imperative and so served to terminate the act. In one extreme instance, illustrative of this condition, a record of continuous sexual connection for four hours was recorded, while a record of half an hour to an hour is not unusual. In these latter extreme instances, however, it may be, and not infrequently it is found, that, although priapism persists, it is no longer possible for the individual to excite his sexual center sufficiently to cause ejaculation to occur. In this connection it is well to emphasize the fact that questions in many cases should be asked bearing directly on the function of ejaculation itself. It may be found to be associated with pain, perhaps very acute or with local or more or less general discomfort or disturbance. Then again the emissions themselves may have at times been bloody or so stained. Emissions described as profuse in volume are more apt to be normal than otherwise, but ejaculations followed by a scant or by no discharge are a pathological phenomenon of importance, indicative of a crippling of the expulsive function.

Inquiry as to the previous existence of syphilis should be made, and, if there is any evidence pointing toward ataxia or the existence of a spinal lesion as a cause for the sexual disability, that should be recorded. The previous existence of perineal traumatism, septic conditions, typhoid, or other debilitating illness or dyscrasia should be noted.

With reference to the physical and special examinations to be made after the clinical history has been obtained, the evidence derived from the sense of touch in connection with the digital examination per rectum is of the greatest importance. In fact, unless a surgeon has such a trained touch, his diagnoses in the great majority of these cases are so inaccurate as to be little better than guesswork. Guyon used to say that a genitourinary surgeon should be able to see with his fingers, a truth so manifest that it should be classed as an axiom. Still, as far as the rectal touch is concerned, very few seem at all skilled or accurate in its use. I make this statement from my experience as a postgraduate teacher and also as a teacher of those just graduated, who occupy the positions under me of hospital internes. Very few indeed seem to be able to differentiate what they feel at all intelligently or accurately. Most class everything felt as simply prostate. Very few claim to be able to feel the seminal vesicles at all in any case. In the absence of practically all such skill, there is little use in expecting that a differential diagnosis could be drawn in case a lesion should exist in connection with any organ coming within the range of the feel. In order to develop accuracy in this particular, one's finger should first of all have some degree of pliancy. Next, the technique of the feel should be mastered in order that the tip of the finger may be able to attain the maximum degree of reach and of rotation. Then it is absurd to suppose that the finger tip can diagnosticate pathological conditions before it has become thoroughly acquainted with the varying degrees of feel associated with normal conditions.

In teaching I find that few among the uninitiated ever even think it worth while to digitally examine any cases except those in which they are told marked lesions exist. My advice, however, is to first practise the touch on as many normal cases as possible, and not to try to examine the pathological ones until the examiner has attained to some degree of proficiency in the technique, and until the feel of normal conditions is thoroughly recognized.

All the large group of sexual disorders which depend for their existence on a pathological condition of the seminal vesicles have to be diagnosticated by the feel presented to the finger tip introduced per rectum. The skilled finger does much more than simply diagnosticate the existence of a lesion. It is able to differentiate between the forms of lesions as well as the grade and the chronicity of a given form. Nor does the function of the skilled touch terminate here with the completion of the diagnosis. It has to be called upon further in connection with prognosis, and, most important of all, it plays the major rôle in both the palliative and the radical or operative forms of surgical treatment.

Stripping and massage of the seminal vesicles, the treatment I introduced to the profession eighteen years ago, is now so well established as to require no special mention. My operation of seminal vesiculotomy, a detailed summary of which appeared in an article in the MEDICAL RECORD, October 30, 1909, has proved itself at my hands to be a most satisfactory and radical operation in dealing with very severe and advanced lesions, for the cure of which the more palliative non-operative treatment of stripping and massage is not adapted. I feel warranted in making the preceding statement as to the great value of seminal vesiculotomy because of my wide experience with the procedure, having to date operated upon 224 cases without any mortality. In 95 per cent. of these cases the results have been satisfactory, both to myself and to the patients operated upon. In the small minority of cases the results have not been bad but negative, that is, the operation has not accomplished enough to have made it worth while. In most of these latter cases it has been subsequently discovered that some unrecognized dyscrasia coexisted sufficient to account for the negative results. Although the profession has shown much interest in this operation, comparatively few have made a trial of it, and most of those who have done so have been students of mine, who had previously had much experience in a close observation of the procedure. The reason for this is because the operation is in great measure performed under the guidance of the sense of touch, rather than that of sight, and very few surgeons have trained their sense of touch sufficiently to allow their trusting to its guidance in the performance of seminal vesiculotomy, or in fact of any other operation.

It is this same reason which has prevented and always will prevent the general adoption of litholapaxy as the operation of choice in the vast majority of uncomplicated cases of vesical calculus. The surgical rank and file stand for cutting into the bladder, on the ground of seeing both the stone and what they are doing, while the few skilled in the sense of touch get radically curative results with little danger or discomfort to their patients through a simple crushing of stone and washing out of the débris.

A LATENT HYPERNEPHROMA WITH A SOLITARY METASTASIS IN THE SPINE.

BY A. E. GARROW, M.D.,

AND

C. B. KEENAN, D.S.O., M.D.,

MONTREAL,

ASSISTANT SURGEONS, ROYAL VICTORIA HOSPITAL.

THE patient, J. W., aged 49 years, entered the Royal Victoria Hospital on September 23, 1904, under the care of Dr. Hamilton, complaining of pain in the dorsolumbar region of the spine with complete paralysis of his legs, and gave of his illness the following history: In October, 1903, he commenced to suffer from slight pain in the right upper quadrant of the abdomen which was often accompanied by gastric distress or even vomiting. In January, 1904, while under treatment by an osteopath, the pain came to be felt more in the umbilical region, and he then noted a loss of power over his rectum. In June, 1904, paresis of his legs commenced which rapidly increased to complete paralysis of the same.

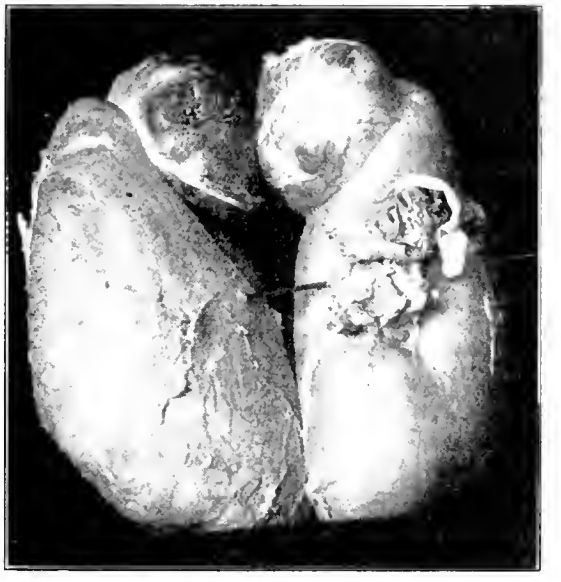

Fig. 1.—Photograph of the kidney as seen from without, showing small tumor mass in the upper pole

Examination of the patient on his admission to the hospital showed no other symptom of disease save the paraplegia above described and as this clearly was caused by pressure on the spinal cord in the lower dorsal region an exploratory operation was performed by Dr. Garrow on September 30, 1904. This revealed a tumor of the bodies of the tenth and eleventh dorsal vertebræ which projected into the spinal canal, compressing the cord. As the complete removal of the tumor with the infiltrated vertebræ was not feasible a small portion was removed for investigation by the pathologist, who later described the minute structure of the growth and termed it a sarcoma.

From the operation onward the patient became gradually weaker and died on February 27, 1905. The urine during the last two months of the patient's life showed a small amount of albumin but never any red blood cells.

Autopsy showed acute parenchymatous nephritis of both kidneys and an empyema on the left side. The tumor of the spine already diagnosed was found to be associated with a second mass, 5 cm. in diameter, on the upper pole of the right kidney, but care-

ful search failed to reveal a third tumor. The discovery of the growth in the kidney was of particular interest and necessitated an investigation of the relationship between the two growths, since the previous diagnosis of "primary sarcoma of the spine" appeared to be erroneous.

The position and the appearance of the second growth are clearly shown in the accompanying

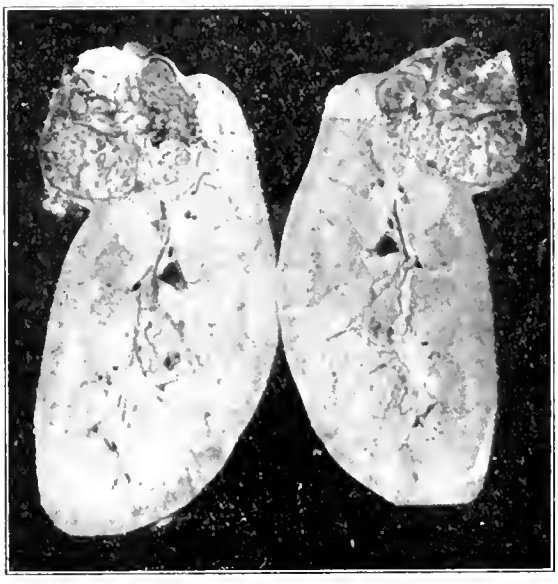

Fig. 2.—Photograph of the cut surface of the kidney

photographs (Figs. 1 and 2). The tumor lay partially embedded in the posterior-superior part of the kidney and the kidney capsule was found to be continuous with the tumor capsule. An endeavor to distinguish between the two microscopically by finding muscle cells proved unsuccessful. The tumor was of soft consistence, varied in color from a dull yellow to a brownish red, and the adjacent kidney tissue showed only such changes as are met with in acute nephritis.

As regards the growth in the spine, this was found to infiltrate the bodies of the lower dorsal vertebræ and form a mass projecting into the spinal canal so as to diminish its caliber though not infiltrating the dura. The accompanying photograph (Fig. 3) shows this plainly.

Investigation of the microscopical structure showed the two tumors to be the same; it will consequently suffice to present a detailed description of the kidney growth alone. The absence of bony trabeculæ in the latter allowed more easy study. The tumor possessed a complete fibrous capsule from which bands passed into the interior and formed a stroma. These bands frequently contained cells resembling those of unstriped muscle and were accompanied by vessels. Toward the center of the tumor the fibrous component was lessened to such a degree that only endothelial-clad vessels occurred. The stroma meshes were of varying size and shape, being sometimes circular and sometimes pillar-like, presumably varying with the plane of the section. Frozen sections demonstrated that almost all the cells were full of fat globules of varying size. A few of the kidney tumor cells did not show this fatty deposit, and it was absent in a considerable proportion of the cells in the spinal tumor. Both intra- and extracellular glycogen globules were found.

The tumor cells themselves were large and clear, having a well defined outline and a rather small round nucleus which was usually central in position. Some of the nuclei stained evenly and deeply, while others were markedly vesicular and contained a nucleolus. The cells were often longer than broad and stood perpendicularly on the fibrous stroma or on the thin-walled vessel to which they were related. In some places the free ends of opposing cells came to touch one another and thus produced a pillar-like

Fig. 3.—Photograph of the tumor in the spine. The latter has been divided by a mesial vertical cut.

arrangement identical with that seen in sections of the adrenal cortex (see Fig. 4). When the free ends did not come in contact the space so left appeared as if surrounded by columnar or cubical

Fig. 4.—The microscopic characters of the portion of kidney tumor which shows the columnar arrangement of cells. X 700.

cells and simulated the lumen of a tubular gland (see Fig. 5) or, in the larger examples, simulated cyst formation (see Fig. 6). Intermediate sizes were also seen. Some of these spaces were empty while others contained leucocytes or normal or disorganized blood. Occasionally inward projections

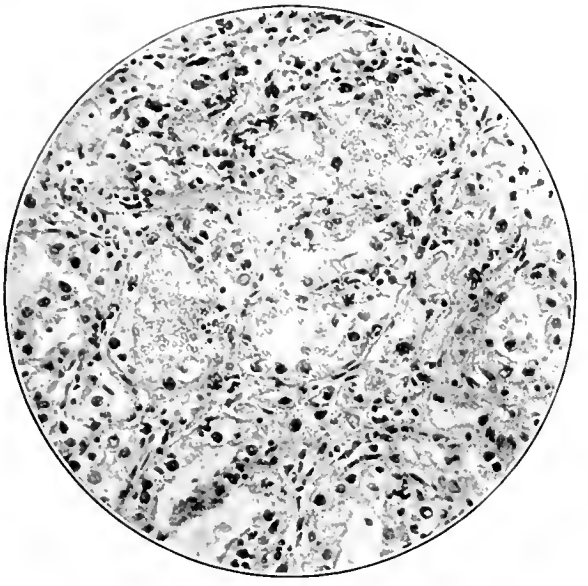

Fig. 5.—Portion of tumor showing acinous arrangement. X 350.

of the cyst walls were seen, and produced the appearance of a papillary cyst-adenoma (Fig. 6). In other places there were large irregularly shaped areas of cells lying edge to edge. Occasionally the cells were isolated, more deeply staining, cubical in shape, and surrounded by a rather hyaline looking stroma. The spinal tumor showed less marked grouping of the cells into columns and there was less fatty metamorphosis, especially toward the periphery of the growth. The cells varied more in size and shape and the nuclei were more variable in appearance.

The two special points of interest lie in the cor-

Fig. 6.—Portion of tumor showing vascular spaces. X 250.

rect classification of the tumor and the relationship between the two. For two tumors of almost identical histological structure to occur in such remote tissues without any other deposits must be very rare.

We judge the kidney tumor to be the primary growth because its structure is more typical and because urinary symptoms were insignificant. The diagnosis would therefore be one of "hypernephroma" as this is the commonest form of primary tumor in the kidney. As pointed out by Hildebrand,[10] and later by Hansemann,[9] endotheliomata and occasionally peritheliomata may occur in the kidney, but these forms are much more rare.

Tumor tissue of the form presented by our case may be derived from three sources—either from the cells of the adrenal cortex, or from endothelial cells of the lymph or blood spaces, or from overgrowth of the lining cells of the kidney tubules. The latter view was first offered by Sudeck[23] and was restated more recently by Stoerck,[22], but has been so ably refuted by Hildebrand[10] that it is only necessary to refer to this very thorough discussion of the subject. The second view—that the source of the tumor is endothelial—was first suggested by De Paoli[5] and Driessen,[6] the latter finding an almost identical tumor in the humerus from a patient who had no kidney disease—at any rate within fourteen months after the operation on the arm. The first view—that the tumor rises from adrenal cells—is substantiated by Loewenhardt,[13] Albrecht,[1] von Bergman,[25] Israel,[11] and Kuster,[12] who showed that a hypernephroma can give rise to a metastases without producing any other sign or symptom.

In 1894 Hildebrand reported three kidney tumors which were very like those of De Paoli and Driessen, but he classed them as peritheliomata because he regarded them as having arisen in the cells lining the perivascular lymph spaces. A careful study of the normal adrenal convinced him that it is built up in the same way; he found a pericellular reticulum both in the tumors and in the adrenal, just as had been noted by Arnold[2] and Flint.[7] He also found that the adrenal cells may present a gland-like lumen. This finding was confirmed by Pfaundler,[18] Marchand,[15] and Stilling,[21] who investigated not only the human adrenal, but also the the adrenal of the horse and dog. Stilling endeavored to prove that this gland-like lumen was a lymph sac. Hildebrand, in agreement with Rauber,[19] noted that the adrenal may contain capillaries clothed by two layers of endothelium, the outermost layer consisting of cells which would simulate peritheliomatous change if they proliferated. This close relation of the adrenal cells to the blood-vessels and the fact that the cortex develops as a perithelioma were pointed out by Brunns,[24] and verified by Braun[3] and Gottschau.[8] Hildebrand points out that this conception of the adrenal and of the hypernephroma is not vitiated by the view that the adrenal cells are mesothelial in origin (mesoblastic), as expressed by Janosik and Pfaundler[18] and accepted by Minot.[16] In other words, we would expect tumors arising from adrenal cells to present the structure of a perithelioma, just as do the tumors arising in the carotid gland (Paltauf[17]).

Hansemann[9] also considers that many of the so-called Grawitz tumors are endotheliomata, and refers to the minute hemangiomata and lymphangiomata which are occasionally found in the kidneys at autopsy in support of his view. Lubarsch,[14] on the other hand, strongly criticises Hansemann's conclusions, bringing forward all the evidence which supports the views already mentioned.

More recently the discussion was centralized on the problem of the genetic relations between hypernephromas and adrenal tissue, and a recent contribution by L. B. Wilson and B. C. Wilson[26] deals mainly with the idea that the Grawitz hypothesis is

as unsatisfactory as the Stoerck theory. Attention is drawn to the heterogeneous tissue-types which go together to form the complex known as hypernephroma, and the deduction is drawn that a renal tubule origin is inadmissible on that ground alone. The developmental sequence of the kidney and adrenal is demonstrated to be associated with the opposite sides of the Wolffian body, so that the adrenal cortex is not likely to become included in the kidney from anatomical grounds. On the other hand, islands of Wolffian body may be seen to come into close connection with the permanent kidney. Further, there is the fact that the normal adrenal never shows tubule or papillary formation, whereas the hypernephroma does. Wilson concludes that the adrenal rest is of Wolffian origin, and that the hypernephroma arises from islands of nephrogenic tissue (primitive renal blastema) and has no connection with an adrenal rest at all.

Davis[4] reported a case which he considered as endotheliomatous histologically and probably mesotheliomatous in origin. In discussing the question of adrenal cell origin he inclines to favor the view that the observations of Steinke on hypernephroma in the adrenal glands of horses and cattle form the only real objection to Stoerk's hypothesis.

Sisson,[20] arguing from the chemical nature of the fat contained in the hypernephromata of cattle and of the Grawitz tumors in man, does not agree with Steinke in considering that there is any parallelism between the two, and does not consider that such observations in veterinary pathology supply a decisive argument one way or another. He further points out that there is no very definite chemical difference between the fats of a degenerating kidney and the fats of an adrenal tumor, although he finds that the presence of doubly refractive crystals uniformly distributed through areas in a section is much more characteristic in adrenal adenomas than it is in a Grawitz tumor.

The conclusions to be drawn from the discussion presented by the literature seem to be that hypernephromata and endotheliomata (*i. e.* hemangio-endotheliomata and lymphangio-endotheliomata) do occur in the kidneys as tumors of varying size and malignancy; that peritheliomata cannot be differentiated from hypernephromata by their morphology, and that endotheliomata may present all stages from flattened endothelium to columnar cells, in single or in multiple layers, with lumina invariably present. The site of the tumor, the amount of degeneration, of fatty metamorphosis, of glycogen infiltration, are all points of minor importance.

In the tumors of the present case the resemblance to adrenal cortex is evident, and the lumina which are present here and there are presumably of the nature of lymph spaces. Where blood is present this seems to be the result of accidental extravasation. The growing edge of the spinal tumor shows a more sarcomatous appearance.

The clinical history shows that tumors of this kind may give rise to metastases before they make their presence suspected either by local pain or by hematuria.

PERNICIOUS ANEMIA CAUSING SPINAL CORD CHANGES AND A MENTAL STATE RESEMBLING PARESIS.*

By CARL D. CAMP, M.D.,

ANN ARBOR, MICH.

CLINICAL PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM AT THE UNIVERSITY OF MICHIGAN.

J. E. M., age 46; German; married; occupation, a merchant; was admitted to the Hospital of the University of Michigan, on November 14, 1911, and the following history was obtained from him and his physician, Dr. Bassett of Grand Rapids. His father died of apoplexy and his mother died of pneumonia. His brothers and sisters are well, and there is no history of any insanity or nervous affection in his family. His wife and all his children are well. The patient had typhoid fever in 1885, but no other serious illness in his lifetime. He particularly denied having had any venereal disease and there was no reason to suspect that he had had. He used no alcohol or tobacco and was never addicted to drugs. About three years before coming to the hospital he rather suddenly began having some difficulty in walking of about the same character as he had on his admission. This had not increased or diminished in that period. Aside from this he complained only of some indigestion and constipation and, at times, of cramp in the muscles of the legs. His physician stated that at times he has had attacks of ill temper in which he broke furniture and which frightened his family. He explained these attacks by saying that after the typhoid fever he developed a violent and uncontrollable temper. He said that he had but little trouble in his home, however, until a physician told his family that he was dangerous, after which they took elaborate precautions, bolting doors carrying revolvers, etc., which irritated him.

On his admission to the hospital he appeared somewhat emaciated and nervous, but mentally normal. His memory was good and he seemed intelligent, good natured, and had no hallucinations or delusions. He walked with a spastic, ataxic gait which was made much worse by closing the eyes. He could stand well with his eyes opened, but swayed

*Read before the Detroit Society of Neurology and Psychiatry, December 7, 1911.

and would fall with his eyes closed. There was no paralysis anywhere, but flexion of the thighs on the abdomen was weak. The pupils reacted normally to light and in accommodation. There was no extraocular palsy and no nystagmus. There was no paralysis of the face or tongue. The masseters contracted normally. The supraorbital reflexes were present. The special senses were apparently normal. Deglutition was normal. The speech was somewhat slurring in character, but this might have been due to a German accent or to the ill-fitting false teeth that he had. The biceps and triceps jerks were normal and equal on the two sides. There was no ataxia or intention tremor in the finger-to-nose test and there were no forced movements. All forms of sensation were normal in the upper extremities. The knee jerks were diminished and the Achilles jerks were not obtained on either side. Tactile and pain sensibility was normal in the feet, but there was a complete loss of sense of motion and position in the toes on both sides. Plantar irritation caused a dorsal movement of the toes on both sides. There was normal tenderness of the tendo Achillis on pressure. No atrophy or deformity of the hands or feet was observed and there was no deformity or tenderness of the spine. The nerve trunks were not tender to pressure. A general physical examination made at this time showed the thoracic and abdominal organs to be normal. The blood pressure was 120. The examination of the urine showed no abnormal constituents. The blood examination showed red blood cells 2,900,000 per cmm., leucocytes 7,300, hemoglobin 80 per cent. The differential leucocyte count showed polynuclear 42 per cent., large lymphocytes 17 per cent., small lymphocytes 12 per cent., eosinphiles 6 per cent., mast cells 2, transitionals 3, degenerate type 18 per cent. The Wassermann reaction was reported negative by Dr. Ide, from the State Psychopathic Hospital. He was given Fowler's solution 5 minims t.i.d. and Blaud's pill, 5 grains t.i.d.

A lumbar puncture was done October 31, 1911, and 15 c. c. of cerebrospinal fluid withdrawn. It was under a low pressure and was clear and colorless. Lymphocytes were four per cmm., counted in a counting chamber immediately after withdrawal. The Noguchi butyric-acid reaction was negative; also both phases of the Nonne-Apelt reaction. The carbolic acid test of Pandy was negative. Reducing substance was present in slightly greater amount than usual (1 c. c. Fehling's solution completely reduced by 9 c. c. cerebrospinal fluid). Acetone was absent. The Wassermann reaction was negative.

November 2, 1911. He complained during the night of severe pain in both sides of his abdomen, but none in the center. It lasted from midnight until 5 A. M. There was no nausea or vomiting. An examination similar to the one above detailed showed no changes in his condition.

November 3, 1911. The patient much excited. He says that: he "has discovered the key to his condition," he "can be cured," "Christian science is wrong and the doctor is right," he has "ataxia," "ataxia is something that is all over," "he can show the doctor how to build hospitals and cure everybody." He is much exalted and it is impossible to fix his attention on anything outside of himself. His speech is clear. He pronounces test words "truly" "rural" well, but repeats "third riding artillery brigade" as "third riding artillery parade" and gets the last word wrong on repeated attempts, although he can pronounce the word "brigade," by itself, normally. He is perfectly oriented and knows the day of the week and the date, and can give a fairly good account of being in the clinic the day previous.

November 5, 1911. The blood examination showed the same condition as at previous examination.

November 6, 1911. The patient says that "he has a new theory of disease that will revolutionize the world." He believes that he has "the key to the diseases." He is very positive of this. Looking at a chair near the bed, he states, "As sure as this chair stands there; and this chair was built according to the same theory by which I expect to revolutionize the world." He believes that through this theory he is going to become great. He says that he is not as yet ready to reveal this theory, but some day when the medical staff of this hospital can get together he will give them the secret. He is very cheerful and talkative, recognizing all the doctors by name and calling them to him to express his ideas. In addition, he writes long statements of his ideas to be sent to them and to the newspapers.

From the 7th of November on he frequently refused to take his medicine, saying that it was poison, but gave no reason why any one should want to poison him. He was discharged from the hospital November 14, 1911, having continued in about the same mental and physical condition during the previous week except that for one day he was depressed and sullen because he was refused permission to lecture to the other patients. His treatment with arsenic and iron was kept up during his stay in the hospital. Before leaving he was examined by Dr. Hewlett, Professor of Medicine at the University, whose blood findings were 3,700,000 red blood cells, 5,500 white blood cells, hemoglobin 87 per cent. Differential leucocyte count: polynuclears 63 per cent., lymphocytes 26 per cent., transitionals 1.2 per cent., eosinophiles 3 per cent., basophilos 6 per cent., degenerate 5 per cent., many platelets, marked poikilocytosis, and some polychromasia. Dr. Hewlett's conclusion was, "Pernicious anemia, probably in the stage of remission."

The examination in the above case pointed to lesions in both the posterior and lateral columns of the spinal cord; the former shown by the ataxia, Rombergism, sensory changes, and lost Achilles reflexes, and the latter by the spasticity and the positive Babinski reflex. The positive Babinski and spasticity would preclude the diagnosis of uncomplicated tabes, as would also the absence of any change in the pupillary reflexes, and the absence of any characteristic crises, lightning pains, and bladder disturbance. If a tabo-paralysis were thought of we would still have to account for the absence of the Argyll-Robertson pupil and the negative Wassermann reaction. The negative findings in the cerebrospinal fluid are almost conclusively against the diagnosis of paresis or any syphilitic or parasyphilitic disease of the brain or spinal cord. There was no history obtainable of any toxic factor, such as lead or alcohol, as a cause of the spinal cord changes.

That pernicious anemia can cause changes in the central nervous system, and especially in the posterolateral columns of the spinal cord, is well known through the writing of Putnam, Burr,[1] Collier,[2] Russell, Clark,[3] Lloyd,[4] Nonne,[5] Henneberg,[6] Crouzon,[7] E. Miller,[8] and many others of all

nationalities. Fewer authors, however, have called attention to the mental symptoms, though Addison and Zichen have mentioned some mental changes in describing pernicious anemia.

Marcus,[9] in 1903, described a case so similar to the one reported here that I present an abstract of the important features: The patient was thirty-seven years old, with no history of syphilis or alcoholism. He rather suddenly developed delusions of grandeur, wanted finer lodgings and bought large quantities of merchandise for which he could not pay. His examination showed the pupils equal and reacting to light and in accommodation. There was no speech defect. I quote: "He was difficult to keep quiet in bed. Always wanted to see the doctors to talk over his condition and gave long, mixed-up, quasiscientific explanations of his condition, his circumstances, and his plans for the future. When the doctors were tired of listening and went away he would write out his ideas and send them. He had some signs of affection of the spinal cord, but when asked he complained of nothing, but said he had been smoking too much and only needed rest. He was well oriented for time and place and had no hallucinations or illusions." He was treated with arsenic and completely recovered.

The author speaks of the resemblance of the condition to paresis, but rules out such a diagnosis by the absence of a specific history, the sudden onset and the favorable termination. He concludes by saying, "It is of great importance to know that a condition so closely resembling general paralysis can be caused by pernicious anemia." In the following year, Pickett[10] published a paper on the "Mental Symptoms Associated with Pernicious Anemia" in which he mentions five cases, but only describes the mental state in one of them. In this case the patient became suddenly delusional, said that his wife had tried to poison him, that the nurses and doctors were in a conspiracy against him, his hands exuded poison, etc. Pickett states that "the patient was not disoriented and could talk clearly of other matters." He tries to classify it as a case of Meyment's amentia of the symptomatic type.

Recently Siemerling[11] has recorded another case of spinal cord changes and psychosis occurring in pernicious anemia, of especial importance because the necropsy findings and also the histological examination of the brain and spinal cord confirmed the clinical diagnosis. The symptoms in this case are very similar to those in the case reported in this paper. In Siemerling's case the patient was thirty-nine years old. He had had syphilis ten years before and had used alcoholics up to six years before his illness. There were signs of posterolateral sclerosis, due apparently to the anemia, which was of the pernicious type. The red blood cells were 2,800,000, with megaloblasts and marked poikilocytosis. The first mental symptom noted was causeless fits of bad temper. Later he became fretful and somewhat sad because he thought his wife would not understand and forgive his attacks. After his admission to a hospital he would not take his medicine one day "because the doctors were trying to poison him." The next day he told his brother that he would not take his medicine when he was not sick; he was only sick in his imagination and no doctor could help him. "His wife was good to him, but could not forget his fits of temper." When his brother asked him if he was being poisoned he replied evasively by an epigram. He knew his location, the date of the month, day of the week, etc., and his doctor's name. He answered questions, said that he felt good, had no pain. He believed that he knew what was the matter with him better than his physicians, for he said that "the stiffness was due to having glass inside him." He gradually grew worse and died.

The spinal cord showed degenerative changes in the posterolateral tracts typical of pernicious anemia. The brain showed no atrophy, no degeneration, and no changes in the blood vessels. Siemerling would ascribe some of the mental symptoms in this case to alcohol, but there were none of the symptoms commonly alcoholic in origin, such as tremor-hallucinations, disorientation or fabrication, and the patient had stopped using alcohol six years before his illness. The patient had had lues ten years before, but the diagnosis of paresis was in this case entirely ruled out by the negative autopsy findings.

It would seem that the mental symptoms shown by these patients were very similar in each case: attacks of anger usher in the cases, but accompanied by some feelings of regret after they have passed. Delusions of being poisoned are frequent, but the delusions are entirely unsystematized. Mental exaltation is present with grandiose ideas, especially with respect to his own condition. There is no disorientation for time or place, no memory defect, no hallucination or fabrication such as seen in Korsakoff's syndrome. The mental state most closely resembles paresis, though there hardly seems to be as much intellectual disturbance as is usual in any case of dementia and the anger and suspicions are rather foreign to the usual paretic type of case.

In the case reported and in those quoted there were no pupillary signs, optic atrophy, or convulsive seizures. According to Van Wart,[12] these phenomena may also be caused by pernicious anemia so that there may be cases in which these symptoms might be combined with the above-described mental state and so lead to even greater difficulties in diagnosis. It seems to be of scientific interest as well as the greatest practical importance to know that pernicious anemia can be the cause of a syndrome of nervous and mental symptoms that so closely resembles paresis that a clinical differentiation between them cannot be made with certainty without the examination of the blood and cerebrospinal fluid.

DIAGNOSIS OF OBSCURE CONDITIONS OF THE COLON WITH THE AID OF THE RONTGEN RAYS.*

By FRANK C. YEOMANS, M.D.,

NEW YORK,

SURGEON, PENITENTIARY HOSPITAL; ASSISTANT SURGEON N. . POLYCLINIC HOSPITAL.

RONTGENOLOGY has greatly enriched our knowledge of the physiology and pathology of the digestive canal. In recent years the rays have been applied in the domain of diagnosis of obscure intestinal lesions where it is on a par with and, indeed, often exceeds in value the exploratory laparotomy without incurring the risks of the latter. The Röntgen rays are absorbed by the tissues of the body in proportion to their density. The denser the object the darker is the shadow in the print, which serves to outline or differentiate one organ or tissue from another. Evidently, then, a radiograph of the abdomen without previous preparation of the patient would be worthless as it would not differentiate, or at best would only show here and there a light area (collections of gas) or rarely a dense tumor.

Various agents have been used to bring the hollow viscera out in contrast. At first sounds as of rubber or lead were tried but discarded as impractical except for the ureters. Next came in favor distention with air, *e.g.* inflating the stomach by a Politzer bulb attached to a stomach tube *in situ*, or the colon by air introduced through the rectal tube. The disadvantages of this method are that the definition of the shadows made by air is not clear and that the distention distorts the normal relations of the organs. Still, inflation has its uses, though limited, in the diagnosis of tumors of the colon, particularly to differentiate intra- from extra-intestinal growths.

Cannon[1] was the first to conduct *x*-ray experiments on live animals (cats) during normal digestion, using bismuth as the insoluble medium, opaque to the rays. He gave a meal in which bismuth was mixed and thus observed the filling and emptying of the stomach. Later he and many others[2], both here and abroad, extended the experiments with bismuth and other insoluble media, observing the progress of the ingesta through the entire digestive tract of both animals and man. Thereby the topography, relations, physiology, and pathology of these organs have been established on a basis far more scientific than was hitherto possible.

Apart from the duodenum and terminal segment of the ileum, the radiograph adds little to our knowledge of the small intestine. Its greatest value lies in observations upon the esophagus, stomach, and colon and it is to the colon especially to which I wish to call attention.

There are two ways of filling the colon with bismuth: by ingestion (bismuth meal) and by clyster. To employ bismuth by mouth for pictures of the colon is tedious, entails infinite patience and cooperation on the part of both radiographer and patient, and besides is usually unnecessary as will be shown later. A series of plates must be taken and even in normal individuals the best one can do is to strike an average as to the period of time that must elapse from the ingestion of the bismuth till its appearance at conventional points in the intestinal tract.

*Read before the Harlem Medical Association, January 3, 1912

If the bismuth clyster should fail to establish the diagnosis, the meal should be insisted upon as it is invaluable for locating obstructive lesions above the cecum, particularly in the terminal ileum and pylorus.

Fortunately this will rarely be necessary, as experience teaches that the vast majority of intestinal conditions for the diagnosis of which the *x*-rays are indicated are located in the colon. The method of choice, then, is first to employ the clyster, which is simple in technique, requires little time, and demonstrates at once the abnormal point or points, if any, in the colon. The writer has reached this conclusion not on theoretical grounds alone, but from an experience based on a large number of observations.

The technique, briefly, is as follows: The preparation of the patient is of prime importance. Its purpose is to secure an empty colon. Feces, especially scybala, obstruct the passage of the bismuth and render good radiographs impossible. The patient is placed on a light diet for forty-eight hours. Castor oil, 1 ounce, is given each night and a full dose of salts, magnesium sulphate ½ ounce, or magnesium citrate 6 ounces, the following morning. No enemas are necessary. Ten to fifteen minutes before the exposure a clyster of bismuth subcarbonate suspension is administered slowly from a fountain syringe through a short nozzle, the patient being preferably in the Sims' posture, though the knee-chest or lithotomy positions may be used in certain cases. The bismuth clyster always traverses the colon to the cecum unless prevented by a real mechanical obstruction—kink, stricture, growth, or feces. The exposure is made with the patient lying prone on the plate. Another radiograph should be taken at once in the vertical position. Should these not prove satisfactory the examination should be repeated at a later date, using the clyster alone or the bismuth breakfast and later the enema if the ingested bismuth is markedly delayed at any point

In any case the order of the examination is:

A. Clinical, including an accurate history; inspection, palpation and percussion of the abdomen; direct inspection of the rectum and sigmoid by the pneumatic, electrically lighted sigmoidoscope; examination of stool after a test diet; discharge for ameba and tubercle bacilli; a Wassermann test of the blood if there is a history of lues or if stricture is present, and a urinalysis of a twenty-four-hour specimen. In the vast majority of cases some one or a combination of several of the above procedures will establish the diagnosis. For example, the colonoscope, when it can be passed, and it usually can, will detect any lesion in the segment of bowel below the apex of the sigmoid and fortunately most diseases of the large intestine are located here.

B. Radiographic. Because of the inconvenience and necessary expense, the physician will resort to the Röntgen rays in obscure cases only; those that still baffle us after exhausting all the routine methods. The radiograph, then, will often be invaluable, a revelation indeed.

The symptoms and signs calling for a Röntgenological examination, after failure of the usual clinical methods, are: (*a*) Pain—in addition to that often present in the epigastrium and common to many an abdominal irritation—colicky or distensive in character, in close association with and dependent upon the particular part of the colon involved (*b*) Constipation—with or without symptoms of

chronic autotoxemia; the higher the obstruction in the colon the greater the toxemia. (*c*) Tumor—palpable or suspected. (*d*)—Abnormal constituents of stools—mucus, pus, or blood.

C. In the presence of an abdominal tumor inflation of air may enable one to determine whether the growth is intra- or extracolonic.

D. Examination under general narcosis or with the patient submerged in a hot bath. Bimanual examination under general anesthesia is carried out by inserting the two first fingers into the rectum, making counter pressure above the pubes with the other hand. With two fingers the examiner can reach about one inch higher than with one finger and growths in the lower limb or sigmoid can be felt through the anterior rectal wall. By changing the position of the patient, as from back to side, a wider area can be palpated as in the search for movable tumors.

E. Finally, in cases of sufficient severity, the exploratory incision must be resorted to, with consent on the part of the patient and preparation by the surgeon to carry out any operative procedure that may be indicated.

Interpretation of the plate.—It is axiomatic that the Röntgenologist establishes facts which the clinician must interpret. The experienced Röntgenologist does not desire and in practice I have found it best not to give him a detailed history of the patient, but simply to call attention to the salient features, as previous operations, etc., and to the particular part one wishes emphasized. Then interpretation of the plate is without bias. The physician, with the advantage of the knowledge of his own clinical findings, confirms and corrects the radiographic diagnosis. It is not surprising that the latter is sometimes incomplete. This, however, does not detract essentially from the value of the picture to the clinician. The radiograph almost invariably shows the site of the lesion and its character—kink, growth, etc.,—and the physician must gain accuracy in determining its nature—tuberculosis, syphilis, carcinoma, etc.—by experience in harmonizing subjective symptoms and clinical findings with the radiographic facts and observations at operation. In proof of the fact that accuracy of diagnosis can be developed to an almost infallible degree, I need only to cite the recent work of Drs. Clairmont and Handk of Jena in which there was not a single error in one hundred consecutive cases of stomach lesions as proved at operation.

In cases requiring surgical intervention this is invaluable, for it enables one to plan his operation in advance and to attack directly the diseased part, thereby saving much time and needless handling of viscera, which spell shock. Moreover, the radiograph will often give a cue of a lesion, particularly bands or adhesions so common about the colon, which, without its aid, might be readily overlooked even at operation.

Our knowledge of the pathology of the colon will also be invaluable in this connection. Knowledge of the possibilities will suggest the probabilities. For instance, angulations of the colon may be due to bands or adhesions from inflammatory processes, as sigmoid to tube or ovary, or two segments of bowel may adhere to each other; or, again, there may occur ptoses of any part or of the entire colon (and flexures), which may be tremendously lengthened and assume many forms roughly classified according to the fancy of the observer, as V-shaped, M-shaped, etc.

Exaggeration of the angles at the hepatic and splenic flexures may be apparent only as the shadow of the ptosed transverse colon may coincide with those of the upper ends of the ascending and the descending colon. To avoid error one has only to remember, however, that the transverse colon is on a more anterior plane. If possible determine the length of the sigmoid, bearing in mind that a long obstructive sigmoid may be associated with a normal colon.

A tumor may occlude the bowel in part and cast a narrow shadow like a stricture; or, crater-like, give a characteristic worm-eaten appearance. If a tumor is suspected, but not demonstrable by the bismuth clyster or palpable, a bismuth meal will be helpful.

Strictures usually begin in the rectum. When their calibre is so narrow that a small tube cannot be passed through them to inspect and define their upper limits, a radiograph must be taken immediately after administering a bismuth enema. This is imperative in anticipating rational surgical intervention.

Illustrative Cases.—The appended cases selected from a large number illustrate the value of radiographs as an aid to diagnosis of obscure conditions of the colon. These cases are suggestive only and are presented in the hope that they will stimulate others to employ the *x*-rays to clear up the diagnosis in that large and pitiable group of patients that goes from hospital to hospital and from one physician to another without obtaining relief. Experience, judgment, and skill are requisite on the part of the Röntgenologist to secure good results, especially in obese subjects. All of the radiographs were made by Dr. Lewis Gregory Cole, to whom I am greatly indebted for his kind cooperation.

Case I.—Mrs. C., widow, no children, aged 40 years, was referred to me in March, 1908. Chief complaint constipation, discharge of blood and pus from rectum, and pain over right iliac fossa. No history of lues. Examination showed a stricture two and a half inches above anus which would not admit tip of finger. This stricture had been cut five years before and again three years later, but as after-treatment was neglected it had recurred. By means of gradual dilatation with Wales' bougies the stricture was enlarged till a No. 8 could pass. The proctoscope now showed the stricture to be two and a half inches in length, the mucosa above this point being healthy. With an occasional laxative the bowels became regular, the discharge diminished, and the patient gained weight, but the pain persisted in the right side and simulated chronic appendicitis.

December 1, 1910, a radiograph was made (Fig. 4). Radiographic diagnosis: "Cecum is normal, there is apparently no ascending colon, transverse colon traverses abdomen from crest of ilium to a point on left side about opposite third lumbar ver-

Explanation of Plate.

Fig. 1.—Normal colon; C, cecum, the largest diameter of any part of the colon; H, hepatic flecture; T, transverse colon; B, splenic flexure; D, descending colon; I, iliac sigmoid; S, pelvic sigmoid. There is no obstruction at the splenic flexure, for the ascending limb of the transverse colon is on a more anterior plane than the descending colon.

Fig. 2.—Normal sigmoid and rectum. I, iliac sigmoid; S, pelvis sigmoid; R, rectum.

Fig. 3.—Normal rectum (R).

Fig. 4 (Case 1).—C, cecum; T, transverse colon; T, L, loop of transverse colon overlying descending colon; B, splenic flexure; S, sigmoid; X, bismuth in small intestine.

tebra, where it turns acutely down to crest of ilium, then up to splenic flexure, which is held well up in position. Descending colon then goes down behind this loop of transverse colon to the sigmoid. The bismuth has passed freely through ileocecal valve into the small intestine."

The prolapse of the hepatic flexure and consequent angulations demonstrate graphically the cause of the stasis and fermentation in the cecum and explain the cause of the pain fully as well, if not better, than would an exploratory laparotomy.

Case II.—Mrs. R., aged 42 years, mother of several children. Health always good, but has suffered from severe constipation of several years' standing, which is now relieved only by enemata. X-ray findings, February 2, 1911 (Fig. 5). "Bismuth suspension has passed as far as hepatic flexure (H). This was a dispensary patient and she probably did not properly follow directions to empty the colon. Transverse colon traverses abdomen just below umbilicus to a point about two inches above crest of ilium, then turns up to splenic flexure, where it turns on itself and passes down into the pelvis, where the sigmoid turns in extremely long loops almost up to splenic flexure then, turning upon itself again, passes down toward the rectum. This gives three loops on the left side, each overlapping the other. There is absence of bismuth between the rectum and sigmoid."

The proctoscope was passed with some difficulty into the lower sigmoid and so excluded any abnormality in this space beyond a sharp angulation at the recto-sigmoidal junction. The unusually long sigmoid, probably adherent at one or more points, and the fact that the delay was probably low down, as the bowels moved only with enemata, would justify a diagnosis of obstruction in the sigmoid. Unfortunately the patient passed from observation before the diagnosis could be verified by operation.

Case III.—Mr. H., aged 46 years, first consulted me in July, 1910. Always well except for double inguinal hernia and constipation for the past three years. In October, 1909, sigmoidopexy was done for "prolapse of sigmoid." Relief was temporary and three months later he developed "peritonitis." The same surgeon operated again, freed sigmoid and other extensive intestinal adhesions, divided terminal ileum, inverting its aboral end and implanting oral end into rectum by the method of Kelly. Owing to the poor condition of the patient the operation was ended hastily, abdominal wound being closed by adhesive plaster. This opened a few days later and now he has a large ventral hernia. This operation gave prompt relief to the constipation, but now it has recurred in obstinate form with symptoms of severe autotoxemia added. Strong cathartics, enemata, and much straining yield five to six mushy stools containing mucus, but no pus or blood. Proctoscope passed easily twelve inches and showed nothing abnormal, nor the orifice of the ileorectostomy, though diligent search was made for the same.

Explanation of Plate.

Fig. 7 (Case 4).—B, splenic flexure (faint); D, descending colon; S, sigmoid; X, constriction in descending colon opposite umbilicus (U).

Fig. 8 (Case 4).—T, transverse colon; D, descending colon; S, sigmoid, transversely in pelvis; X, constricted area in descending colon.

Fig. 9 (Case 5).—C, cecum; T, transverse colon; D, descending colon; S, sigmoid; X, kink in sigmoid [adhesions (?)]; U, umbilicus.

Fig. 10 (Case 6).—H, hepatic; B, splenic flexure; D, descending colon; S, sigmoid, long loop.

Fig. 11 (Case 6).—D, descending colon; S, sigmoid; R, rectum.

Fig. 12 (Case 7).—D, descending colon; S, sigmoid; X, irregular worm-eaten area.

November 10, 1910.—Radiographic diagnosis (Fig. 6).—"No evidence of a new growth obstructing colon. There are very marked adhesions between the sigmoid and cecum (?) which might readily account for the obstinate constipation of which this patient complains. I am completely at a loss to explain the peculiar loop at the hepatic flexure unless it is a result of operative procedure. The bismuth emulsion has passed to the cecum, giving the outline of the colon for its entire length." Concluding that the obstruction was in the sigmoid, I did an appendicostomy December 16, 1910. Irrigations through the appendix gave prompt relief. The patient resumed work and gained weight, but three and a half months later constipation and toxemia returned. He requested an exploratory operation, which I did March 14, 1911. Omentum was adherent to scar. Terminal ileum was buried in a dense mass of pelvic adhesions. No attempt was made to separate it. Just above the adhesions the free ileum was united to the free sigmoid by broad lateral anastomosis with a double row of continuous sutures. Parietes were closed in layers. Patient reacted well, but developed double pneumonia the next day, to which he succumbed five days later. Urine was suppressed the last twenty-four hours. Bowels moved the second day after operation and thereafter three to four times a day. There were no signs of abdominal infection. Autopsy showed no evidences of peritonitis. Specimen removed consisted of the portion of ileum and sigmoid operated upon intact. The new lateral anastomosis was firmly united. The opening of the old ileorectostomy was so contracted that it would admit a 16 F. catheter with difficulty, and explained the constipation and toxemia. The radiograph was of great value for it showed patent colon. Had the Röntgenologist known the nature of the operation previously performed, he would readily have recognized "the peculiar loop at the hepatic flexure" as bismuth in the ileum, which had passed through the ileorectostomy, and so have located precisely the site of the lesion in a difficult and extraordinary case. In the presence of severe constipation and autotoxemia with a patent colon, the diagnosis of obstruction at some point in the intestinal tract above the colon was simple on clinical grounds alone.

Case IV.—Mrs. R., aged 48 years, consulted me in January, 1911. Had pneumonia thirteen years ago. Birth of her first child twenty-one years ago was followed by "peritonitis," "uremia," and constipation. The latter has persisted to date and has been very severe the past five years, now requiring three cathartic pills at night and an enema in the morning to secure a movement. Hemorrhoids and fissure were operated upon three years ago.

Radiograph, January 26, 1911 (Fig. VII). Findings.—"Bismuth suspension passes up to a point on a level with the umbilicus. There is a long, tortuous loop of colon which passes up to a level with first dorsal vertebra and then turns downward on a line with the umbilicus, where there is apparently a marked constriction. There is a suggestion of the bismuth passing through the constricted area and slight indication of a descending colon and splenic flexure behind the distended loop."

Diagnosis.—"Strong evidence of a constriction of the descending colon on a level with and about two and a half inches to the left of umbilicus. The long, distended loop is sigmoid."

Confirmatory radiograph, January 31, 1911 (Fig. VIII). Diagnosis.—"Bismuth has only passed into the transverse colon. The long, tortuous loop which passed up to splenic flexure in the original plates now traverses the pelvis to the right side. There is partial obstruction of the descending colon near splenic flexure. From the lack of worm-eaten appearance one would be suspicious of adhesions rather than new growth."

Operation, February 10, 1911. As the patient was very stout (180 pounds) it was difficult to see the region of apparent obstruction. Adhesions may have been present, causing obstruction but no growth, bands, or adhesions could be felt. Sigmoid, about three inches in diameter and twenty-four inches long, suggested that this might be the offending part. Accordingly it was united to the upper colon by a broad lateral anastomosis with a double row of sutures. Relief was prompt and the patient's bowels have acted daily since without cathartics.

Case V.—Mrs. G., aged 64 years, very corpulent, first visited me in April, 1911. Twelve years ago panhysterectomy was performed upon her; one year later perineorrhapy, and hemorrhoids were removed five years ago. During the past two years she has suffered from colicky pains, rolling sensations and distention (gas) over left iliac fossa, and severe constipation and autotoxemia. The proctoscope passes easily ten inches and shows mucus in excess and a pale mucosa.

Radiograph, June 16, 1911 (Fig. IX).—Shows entire colon distinctly and quite normal, except in the central part of sigmoid, where there is a kink and absence of bismuth for about one-fourth inch. I am confident that this is the obstructive point, though the patient's age and general condition preclude operation. This view is supported by the fact that forcing oil high in the colon through the pneumatic sigmoidoscope always gives temporary relief and keeps the patient comfortable.

Case VI.—Miss S., aged 23 years, single, delicate, and of enteroptotic habit, but never ill. Constipated since puberty. When cathartics are taken bowel movements are accompanied by severe pains. Enemata return slowly in sections with poor result. Kidneys and spleen not palpable. Iliac regions not tender. Vaginal examination negative. Proctoscopic examination unsatisfactory, as the tube could be passed only to the rectosigmoidal juncture.

Radiographs, February 25, 1911.—Colon appeared normal (Fig. 10), except a long loop of sigmoid, which passes nearly up to the umbilicus. The posterior plate (Fig. 11) shows sigmoid very long, tortuous, and distended and so matted together that it is difficult to differentiate the loops accurately. Radiographically this would explain the symptoms. Operation on March 14, 1911, confirmed the radiographic findings of adhesions, which proved sufficient to cause the constipation.

Case VII.—Mrs. C., aged 52 years, married. When nineteen years of age she miscarried at the second month, became infected, had local peritonitis, and was curetted. Otherwise here health has always been good apart from intestinal troubles. In 1907 she was operated upon for "ulcers of the rectum." In 1908 anterior sigmoidopexy was performed. When she consulted me in October, 1910, she complained of the same symptoms that began in 1907, viz., several morning stools containing mucus; bearing down pains, increased by standing; also a feeling "as if the bowel was compressed down into the rectum." Vaginal examination was negative. Proctoroscopic examination showed a pale, succulent mucosa with marked excess of mucus. Hot enemata of various solutions and of oil gave temporary relief only.

Radiograph, June 1, 1911.—A series of three plates were taken. One of these clearly showed the upper colon to be normal. The other two plates (Fig. 12), with the patient prone, "show an irregular worm-eaten area where the sigmoid joins the descending colon. There is evidence of some lesion at this point, but whether adhesions or growth cannot be stated."

June 16, 1911, I did an exploratory operation. Great omentum was adherent to the scar of the former operation and it covered descending colon and sigmoid, fixing the latter firmly in the iliac fossa. These adhesions were all freed and the raw surfaces inverted as far as possible. Recovery was uneventful and all symptoms disappeared while the patient remained in bed. Later there was some recurrence of pain, but after three months in the country she reports at this writing that she has gained twelve pounds in weight, bowels move once or twice a day with very little mucus, takes no enemata or cathartics, and that the pain is now bearable and only slight in comparison with what it formerly was.

Conclusions.—1. Establish the diagnosis of obscure conditions of the colon, if possible, by the routine clinical methods.

2. The trouble and expense should not prevent the use of the Röntgen rays when indicated.

3. Their use is without risk to the patient.

4. Abnormalities in size, position, angulations, and constrictions (tumor or stricture) are made as manifest as at operation.

5. If operation is necessary it is planned in advance and much valuable time and manipulation saved, which lessen shock.

6. They reduce the number of unnecessary (exploratory) operations; and by establishing an early diagnosis enable the surgeon to perform necessary operations at the most favorable time.

A STUDY OF CARDIOVASCULAR DISEASE IN ITS RELATION TO LESIONS OF THE ABDOMINAL VISCERA.*

By JOHN DUDLEY DUNHAM, A.B., M.D.

COLUMBUS, OHIO.

MEMBER AMERICAN GASTROENTEROLOGICAL ASSOCIATION.

The selection of this title for a discussion was suggested to my mind by the observation of quite a number of patients in whom acute or chronic abdominal symptoms could not be explained during operations performed for their relief.

Not all patients who have acute attacks of pain in the right hypochondrium, over the pylorus, or at McBurney's point are suffering from gallstones, gastric ulcer, or appendicitis. Arteriosclerosis or

*Read before the Columbus Academy of Medicine November 27, 1911.

increased arterial tension, as a result of syphilitic infection, is often responsible for abdominal colic and indefinite distress simulating nervous dyspepsia.

My interest in the subject was first aroused by a patient seen seven years ago. A man of about fifty years was brought into the hospital in a comatose state with a rapid, full, bounding pulse and evident high tension and a distended abdomen. From his family rather an intelligent history of indigestion covering a period of years was obtained. He had complained of pain after food and of waking in the night with abdominal pain, which was relieved by the ingestion of food or soda and by belching. A diagnosis of ruptured duodenal ulcer was made without further investigation and an operation was performed. Thorough and painstaking search of the stomach, intestines, gall-bladder, ducts, etc., failed to show any pathological condition. The patient died at the end of twenty-four hours from cerebral endarteritis.

There is no question that in this case the disturbances ascribed to indigestion resulted from splanchnic irritation and abdominal arteriosclerosis. Cases have frequently been reported in which tortuous sclerosed temporal or radial arteries are found unassociated with abdominal arteriosclerosis. In like manner we may have angina abdominis with abdominal arteriosclerosis without evidences in the arteries accessible to palpation or capable of measurement with instruments. Diagnosis is certain when improvement is obtained by proper medication or when a generally increased arterial pressure or possibly angina pectoris occurs. Fortunately, very few cases belong to this group, so difficult to differentiate. The majority of patients who suffer from abdominal arteriosclerosis have indications which may be easily recognized in other parts of the body.

Many times abdominal pain is the urgent symptom, hence careful study is not directed to the condition of the cardiovascular system. The urine should be carefully studied in cases associated with high pressure. The routine test for albumin is not sufficient, for many times one finds a few red blood cells and many hyaline casts, even when albumin is temporarily absent. When casts, with or without albumin, are found in the presence of acute abdominal pain, a hasty diagnosis of appendicitis or a similar lesion should not be made.

In cases of apparent appendicitis or gallstones with atypical symptoms the physician should hesitate to advise operative interference in the presence of tube-casts and high pressure. Objection is often raised to ascribing any importance to blood-pressure findings because of the variability of results in the use of apparatus and the possibility that the hypertension is only a localized one.

However, any physician may easily learn to estimate the pressure very accurately by palpating accessible arteries in various parts of the body. Palpation of the femoral artery furnishes the most reliable information from which to make deductions in these cases of arteriosclerotic colic. A concrete instance may make more definite this idea.

Case I.—A man of thirty-one years, bartender, married, whose family history was negative, was referred to me May 10, 1910, by his physician for a corroboration, before operation, of his diagnosis of gallstone colic. The patient was strong until eight years ago. He has never used alcohol excessively. Six years ago he was infected with syphilis. One year later he began to have attacks of mildly acute abdominal pain. An appendectomy was performed and a slightly inflamed appendix was found, but his abdominal pain did not cease. Three years ago he had typhoid fever with a complication of pneumonia. For six months he has suffered intermittently with severe abdominal colic. Belching and a sensation of a lump under the upper third of the sternum are experienced during the attacks. Morphine and other analgesics give very little relief and latterly have had no effect. During his last attack his attending physician administered morphine sulphate hypodermically in one-and-one-half grain doses without benefit. The attacks continue from five to twelve hours.

Examination following an attack the previous night showed an hypertrophied heart, the apex displaced one inch to the left of its normal position, cardiac dullness increased to the right. At the second right interspace the second sound is accentuated and the sounds here are irregular. From the second to the fourth ribs on the right side a thrill is felt. Pain is elicited on pressure at the end of the sternum.

There is no increase of pain on pressure under the right costal margin, nor is the pain increased at this point at the height of inspiration. The inguinal lymphatics are enlarged. Palpation over the femoral artery shows a high tension estimated at 210 m.m. The instrument of Faught shows a pressure of 235 m.m.

After an Ewald test meal the contents of the stomach show a hydrochloric acidity of 40 and a total acidity of 60, and no occult blood. The stomach on inflation with air is normally situated, with no dilatation. A diagnosis of aortitis, arteriosclerosis, and angina abdominis from high pressure was made.

Trinitrin relieved his subsequent attacks, while mercurial inunctions and potassium iodide were given for many weeks. As a result he suffered only one mild attack during the last year.

Another case may be noted of a patient about to be operated upon for cholelithiasis, in whom high pressure with acidosis accounted for the colic.

Case II.—A married woman, aged sixty-four years, seen in consultation with her physician and surgeon. The family history is negative. There has been no serious previous illness. Six years ago she had an attack of palpitation of the heart without pain in the arm. Six weeks ago she had angina pectoris with severe pain in the region of the gall-bladder. Two days ago she had angina pectoris with severe abdominal pain, tenderness over the gall-bladder, and uncontrollable vomiting. There is no pain on pressure under the right costal margin. The radial and femoral arteries are full and bounding, and evidently much sclerosed. The diagnosis of the physician and surgeon rests between neurasthenia and gallstones. The urine has not been examined, and upon investigation is found to contain diacetic acid, acetone, and glucose. Lavage shows no food or blood in the stomach. The systolic pressure is 195 mm. Within twenty-four hours this patient suffered an attack of hemiplegia with aphonia and died five months later from cerebral hemorrhage.

The first of these two cases explains the failure to secure recovery after some cases of appendectomy. The cardiovascular disease, which was evidently responsible for the abdominal pain, could not be cured by an appendectomy.

The second patient would no doubt have died after an operation for gallstones, as the arterial pressure was very high and the acidosis marked. No necropsy was secured in this case, but even if one grants the presence of gallstones, operation was contraindicated, and the patient could not have been cured by their removal.

A few years ago, as a result of the work of Crile and others, much attention was given to careful observation of blood pressure before operations. But, unfortunately, the routine examination of the cardiovascular system is not given enough consideration at the present time.

No doubt arterial hypertension and the associated disturbance of the splanchnic nerve account for many failures to cure patients whose appendices and gallstones are removed. Probably unrecognized cardiovascular disease explains some of the unaccountable sudden deaths following operations upon the upper abdomen.

Rosengart* of Frankfurt A. M. has shown that abdominal arteriosclerosis is liable to induce annoying flatulence, painful distention, especially in the right hypochondrium, and occasional colic and eructations, the latter sometimes bringing relief. The patients are irritable and sleep is broken and fitful. Sometimes the condition in the night is improved if the patient eats something. The appetite is good, with a tendency to constipation. The stomach digestion is generally good, with occasionally a little hyperchlorhydria.

Some patients in this class have proctitis with considerable secretion, eczema of the anus, and hemorrhoids, and slight albuminuria may also be observed. Gradually the pulse rate increases and a systolic murmur becomes audible with accentuation of the second aortic sound. The blood pressure rises, and the diagnosis of arteriosclerotic disturbances may be rendered certain by an attack of angina pectoris. Some of these conditions may exist for years and deceptively simulate nervous dyspepsia. The patients are generally men who tell of overwork or high living. Many also complain of dizziness, headache, and weakness of memory.

One striking symptom has been observed in that patients who could formerly take alcoholic drinks develop an intolerance for them. These patients are usually said to have neurasthenia or nervous dyspepsia. Let me add that this symptom-complex is far from an unusual occurrence. The diagnosis of gastric or general neurasthenia is entirely too frequent. Before we are content with neurasthenia as an explanation, we must exclude cardiovascular disease and the intestinal crises of syphilis.

There is another group of cases in which patients have symptoms very suggestive of duodenal ulcer. Nervous symptoms are marked. There is pain after food or there may be pain only in the night. There may be also vomiting and hematemesis and violent colics. In these cases there is abdominal arteriosclerosis with thrombosis of some of the finer arteries.

The presence of occult blood in the stomach contents or feces is at times misleading, as arteriosclerotic colic is often associated with alimentary bleeding. Two cases in my own practice are illustrative.

Case III.—A prominent business man, aged about fifty-one years, consulted me for indigestion. His family history is good. His position involved much anxiety and constant attention to work. He has been perfectly well until the last six months. During this time he has found that regardless of the kind of food ingested he has some distress three to four hours after meals. He wakens every night at 2.30 or 3 o'clock with pain. Food or soda taken at this time does not mitigate the pain. He at times vomits in the night and twice has vomited blood. He is nervous, irritable, and does not remember details as formerly. He had no injurious habits. The abdomen reveals no tender spots and there is no tender spot in the back. The blood examination shows hemoglobin 75 per cent., and slightly irregular erythrocytes. The urine is normal. The stool shows occult blood. The systolic pressure is 165 mm. A tube could not be passed into the stomach on account of a spasm at the cardia.

A diagnosis of duodenal ulcer was made. The patient was treated at a sanatorium in another city for five weeks and returned home with as much pain as before the treatment. My diagnosis was then changed to abdominal arteriosclerosis. Treatment upon this basis has greatly improved his condition, although he has not made a complete recovery.

The history of another patient illustrates the danger of error in making a diagnosis of neurasthenia when the patient has a beginning arteriosclerosis with abdominal symptoms.

Case IV.—In April, 1910, a woman of forty-eight years, whose life had been spent very actively in society and charitable work, consulted me after a diagnosis of neurasthenia had been made by her attending physician. Her father died at eighty years of paralysis; her mother is living at the age of eighty-six and has been an invalid all her life. One sister died during childbirth and one brother committed suicide. She passed the menopause five years ago. The patient never had serious illness except a left-sided paralysis of the face ten years ago, from which she recovered within six weeks. Pain occasionally occurs in the cardiac region, but there has been no angina. There is a history of constipation and hemorrhoids. Pain is experienced in the bowels during and for a short time after meals. She suffers greatly from hemicrania. The examination shows normal reflexes, a blood pressure of 140 mm., hemoglobin 90 per cent. Hyperchlorhydria is shown by examination of a test breakfast. The urine shows a faint trace of albumin, but no casts. The second aortic sound is slightly accentuated; there is tenderness in the right upper quadrant of the abdomen. A right nephroptosis of the first degree is present. A diagnosis of neurasthenia was made and a more simple life advised. Recently she has again consulted me largely on account of increasing nervousness and headache. This second examination after a lapse of eighteen months shows the blood pressure increased to 165 mm. Many hyaline and granular tube casts are found in the urine, but no albumin. There is now pain four to five hours after meals and in the night. The heart has become hypertrophied and the second aortic sound is much more pronounced than upon the first examination. A diagnosis of cardiovascular disease with abdominal symptoms has now been made.

Two remarks are worthy of mention in this case. 1. Neurasthenia is a cloak for many diagnostic errors and should never be considered until every other possible diagnosis is excluded. 2. The sediment of every urine tested should be examined microscopically regardless of the presence or absence of albumin.

*Münchener med. Wochens., No. 20, May 15, 1906.

Interest in this subject will be stimulated if cardiovascular disease with angina abdominis is considered as a possible explanation of obscure disturbances in the abdomen.

Hemorrhoids, proctitis, indefinite pains in the abdomen, the presence of occult blood in the stools are conditions which may at times be explained by increased arterial tension with its associated pathological changes. Many cases of apparent gastric or duodenal ulcer which are not cured by the usual methods are merely cases of arteriosclerotic colic due to a chronic arteritis.

In closing let me emphasize, first, the importance of a microscopic examination of the urine and the estimation of the blood pressure in every patient under observation, and, secondly, the necessity for a broad view in each case, placing every symptom and laboratory finding in its proper position.

PEDIATRIC MEMORANDA.

BILATERAL ANOPHTHALMOS. AMAUROTIC FAMILY IDIOCY.*

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK.

Anophthalmos.—The eight-months-old baby was admitted to my hospital service for severe gastroenteritis. I understood it was abandoned by the parents in an out-of-town home for the blind, and no detailed personal or family history could be ob-

Fig. 1.—Anophthalmos.

tained. Contrary to our expectations or wishes, the patient recovered promptly from the intestinal trouble on suitable change of feeding—it was apparently put in this world to stay. As can be noted from the accompanying illustration (see Fig. 1), the eyelids were normal in development except for their closer proximity. On separation of the lids, instead of eyeballs, a thick, pale membrane was discernible, which yielded to pressure sufficiently to prove the absence behind it of even rudimentary

Fig. 2.—Amaurotic family idiocy

soft visual structures. It was dreadful to watch the infant staring vaguely into distance. It never smiled and its sad and somber facial expression inspired awe and pity. Entirely unaware of its surroundings it would instinctively grope about with its long emaciated fingers for its only friends in creation—the bottle or nipple. We were obliged to pad the frame of its crib to protect the hapless infant against knocks and bruises that it was so prone to receive during its indefatigable search for something to gratify its voracious appetite. After a few weeks' stay at the hospital, the child was returned to its old home.

Fortunately bilateral anophthalmia is an exceedingly rare congenital anomaly—only about one hundred cases having thus far been recorded.

Amaurotic Family Idiocy.—The type of blindness I am about to describe is not quite as dreadful as the aforgmentioned one, since the child afflicted with amaurotic idiocy never lives beyond infancy.* Furthermore, with the gradual degeneration of the cerebral gray substance and ganglion cells, and the progressive development of idiocy, the child is not cognizant of its existence, hence is entirely free from mental or physical pain. This was surely the case with the eleven-months-old baby under observation (see Fig. 2). The patient was the youngest of three children of Austrian Hebrew parents. The older brother and sister are both normal in development. The infant was normal at birth, was breast fed, and grew nicely physically as well as mentally up to about six months of age, when it weighed twelve and a half pounds. It was able to hold its head erect firmly and sat up with ease when slightly supported. Soon after, however, the parents noticed that the child was slowly but surely losing ground. It grew pale, flabby, and less active. When put on the lap, the upper body would fall either forward or backward. Furthermore, the baby lost interest in its surroundings, it rarely smiled, and did so only after special inducements; bright objects no longer attracted its attention, and, as time passed on, it rarely showed inclination even to feed. As usually

*Recently a late form of the disease has been described, especially by Dr. Vogt.

"teething" was primarily blamed for the extraordinary change, particularly since it manifested a tendency to protrude its tongue, and the saliva was profusely flowing from the half-closed mouth. The family physician, noting that the child snored noisily, suggested the removal of adenoids—which was done without the slightest improvement in that direction; and another physician thought that the baby was suffering from rachitis owing to paucity of the mother's milk and put the patient on a liberal artificial diet. It came under my care when nine and a half months old. The aforementioned clinical picture was then more typically expressed. Sure enough, the child did present several symptoms of rickets, such as a widely open anterior fontanelle, prominence of the ribs and the epiphyses, but the deadly stillness of eyes; the grayish white discoloration in the region of the macula, later with the cherry-red spot in the center; the extreme gravity of the countenance, and the pronounced insensibility and muscular atony, eloquently told the woeful tale—another case of amaurotic family idiocy, the sixth under my own observation in a period of ten years! At that time the child was still able to follow a bright light and its hearing seemed but slightly affected. As the father of the baby once served in the Austrian army and was fond of "life" in his younger days, I deemed it my duty to put the child on antisyphilitic treatment, but to no avail. From week to week the clinical features, especially the amaurosis, the defective hearing, and the idiocy, progressively grew worse. The patient finally contracted the grip, which rapidly led to hypostatic pneumonia and terminated fatally within a few hours.

CHRONIC POSTERIOR URETHRITIS, VESICULITIS, AND EPIDIDYMITIS IN MEN BEYOND MIDDLE LIFE.

By MILTON R. PARKER, M.S., M.D.,

CHICAGO.

It is not infrequent that these three conditions exist at the same time in the same patient. The class to which we refer in this paper are honorable, upright men who have homes and families and upon whom no suspicion of immorality rests and from whose history none can be gained. These patients do not belong to the tuberculous class, and gonorrhea is not the etiological factor. In my work I have divided these sufferers into three classes, according to etiology: the tuberculous, gonorrheal, and hyperemic classes. The last, in my experience, is by far the largest class. We shall in this paper deal only with the hyperemic class.

The universal history of these sufferers is about as follows: The patients married some time in the twenties and had normal marital relations for from fifteen to twenty-five years. They had no physical troubles during this period, and their sexual desires were satisfied. At about forty years of age the wife's sexual desires began to wane and in from one to five years completely failed. Since that time the patient's sexual hunger has been totally unsatisfied. Sometimes the history reveals nocturnal erections and emissions and sometimes the mentality has suffered from the constant and persistent demands of an unsatisfied sexual system which, until recently, had been satisfied.

The normal sexual cycle in the male has its initiative in an impulse conveyed to the central nervous system. This impulse may be psychical, as a socalled impure thought, or it may be physical, as some irritation of the sexual organs. Following the impulse, hyperemia of the sexual organs takes place and the cycle terminates with copulation. The intervals between these sexual cycles vary in length in healthful persons, according to their sexual vigor. In all, however, there is a period of complete rest for the sexual organs following each normal cycle, and the condition of hyperemia completely subsides.

For the purposes of this paper an abnormal sexual cycle consists of a cycle not completed by copulation. The initiative is the same as in a normal cycle, though in this class of cases, in a vast majority of instances, the provocative impulse is beyond the control of the patient. In these abnormal cycles the sexual organs are hyperemic, the same as though the cycle has been completed. The cycle not being completed, however, the hyperemia continues, and there is as time goes on no rest for the sexual organs, which are continuously in a stage of hyperemia.

The most constant result of this condition of hyperemic irritation is a posterior urethritis and an increased cell growth, resulting in an hypertrophied prostate. Some cases, however (and these are the cases under consideration in this paper), do not terminate in hypertrophy of the prostate. The posterior urethritis extends by continuity of tissue

Fig 1. Fig 2. Fig 3. Fig 4.

to the seminal vesicles and to the epididymis. These patients give the marital history above mentioned, and the subsequent history of unsatisfied sexual craving followed by the symptoms of posterior urethritis and later those of epididymitis. An examination reveals a chronic posterior urethritis, pus in either one or both of the vesicles, and an enlarged and tender globus major, though some other part of the epididymis may be involved.

So frequently and constantly has the above sequence existed in this class of cases in my experience it would require much stronger evidence than any that now exists to satisfy me that repeated abnormal sexual cycles are not the chief etiological factors in the production of hypertrophied prostates and the conditions especially referred to in this paper.

The treatment of chronic posterior urethritis, vesiculitis, and epididymitis in this class of cases is the well-known treatment for these conditions which has been in vogue for years. But in spite of such treatments, well directed and faithfully executed, a certain number of these cases do badly. The epididymitis will apparently recover, and when the surgeon thinks he has at last conquered the conditions the urethritis will again become active and pus will again appear in the vesicle; treatment is directed to these, and as the surgeon begins to feel that he has the condition under control the epididymitis again lights up and the fat is all in the

fire. A vicious circle has been established, and in spite of the best that can be done with the recognized therapeutic measures and local treatments, some of these patients become wall flowers in the doctor's office, much to his chagrin and their disgust.

In 1903 Cheatwood* of Baltimore reported ten cases of this condition treated by vasectomy. All of these cases promptly recovered and remained well. I have now operated upon eleven cases for this condition with the happiest results in every case. Vasectomy will promptly and permanently cure all of these left-over cases. I do not leave these cases now so long unoperated upon. The patients are always more than satisfied with the results, and as one side, only, is usually involved, only one vas is operated upon; hence the patient is not rendered sterile, and the only objection to the operation is overcome. The reason why vasectomy cures these cases is that a vicious circle is set up; the chronic diseased process is conveyed by continuity of tissue along the vas to each of the organs involved. A vasectomy destroys the vicious circle and the case recovers.

In doing vasectomy I have developed a technique unlike any other of which I am aware. After recognizing the vas and bringing it close to the skin of the scrotum about an inch from the raphæ, the thumb and the index finger of the left hand are pinched together beneath it and a stitch is passed through the skin of the scrotum beneath the vas and very close to it and tied tight in a bowknot. The vas is a very slippery organ and eludes one when one least expects it. This stitch perfectly controls the vas (Fig. 1). A small incision is now made through the skin of the scrotum down to the vas. The stitch prevents bleeding and the vas is readily recognized by its white, silvery color. A ligature carrier is now worked beneath the vas and the latter is brought out through the incision (Fig. 2). Two ligatures are now placed on the vas, and the piece of vas between them is cut away. Usually an inch and a half of the vas is removed (Fig. 3.). The stumps of the vas are now pushed back into the scrotum, the bowknot is untied, and the stitch is tightened, closing the incision in the scrotum: the stitch is then tied in a square knot. A collodion dressing completes the operation. The patient should remain in bed two or three days.

When these cases run their usual course and an hypertrophied prostate results, the removal of the prostate does not always cure the posterior urethritis. In June, 1910, I removed the prostate from a man seventy-three years old who belonged to this hyperemic class. He had suffered many years with symptoms of posterior urethritis. The prostate was removed because, during the latter part of his history, dysuria and incontinence were so preying upon his general health that his life was in jeopardy. He promptly recovered from all the above conditions and resumed his business. The comparatively slight troubles due to the old urethritis he still maintained, but because of their comparative insignificance paid little attention to them. In July, 1911, this patient returned to me for treatment. He had passed a year of energetic business life and with no trouble save the slight discomfort due to his urethritis. About a week before coming to me the second time, upon rising in the morning he could not pass a drop of urine, though he had the usual desire. He went about his business and remained thus employed until 3 o'clock P.M., during which time he had made many unsuccessful attempts to pass his urine. At this time the pain from the pressure of the urine had become so severe that he went home and called a physician. After many useless attempts to empty the bladder the physician took the patient to a hospital, where several other attempts were made without avail to empty the bladder until an anesthetic was given, when the bladder was emptied. From this until the patient came to me a wek later he had no control of the urinary flow. The urine dribbled away all the time. A careful examination revealed a contraction of the neck of the bladder or, in other words, an hypertrophy of the sphincter vesicæ, which was responsible for his urinary troubles. It also revealed a posterior urethritis, pus in the left seminal vesicle, and an enlarged and tender globus major. With the patient under an anesthetic I cut the hypertrophied sphincter, directing the knife with the index finger of the left hand placed against the sphincter through a perineal urethrotomy incision. The sphincter was not completely severed, but was cut sufficiently to allow the index finger to enter the bladder. The finger was then withdrawn and a rubber tube wrapped with gauze until it was the size of the finger was inserted and retained by a stitch. The perineal wound was packed tightly beneath the drain to prevent hemorrhage. If this is carefully done hemorrhage need not be feared. The tube was left in position for ten days, causing the wound in the sphincter to heal by granulation. At the same sitting I did a vasectomy as above described. The patient made a prompt recovery, has remained well since, and has had no more symptoms of his posterior urethritis. This is a case in which the posterior urethritis was followed in the usual way by an hypertrophied prostate. The prostrate was successfully removed. This did not cure the old urethritis, which was followed a year later by an hypertrophied sphincter vesicæ and by vesiculitis and epididymitis.

ABSCESS OF THE NASAL SEPTUM.

By IRVING WILSON VOORHEES, M.S., M.D.,

NEW YORK.

Abscess of the nasal septum occurs as the result of local processes, excoriations, after operations, etc., or as a complication of infectious diseases. One may differentiate a traumatic from a non-traumatic form. The traumatic form frequently causes a hematoma which becomes directly infected through blowing the nose, or the infection enters by way of the blood or lymph vessels. Non-traumatic abscess may come from infection by continuity, such as in erysipelas and diphtheria, or as a metastatic process.

By far the most frequent cause of septal abscess is an injury to the external nose. After a punch or blow there is almost always a fracture of the septum with the formation of a hematoma between the perichondrium and septum. Pyogenic bacteria enter either through a tear in the mucous membrane or by way of the blood or lymph paths and infect the blood-filled sac. In other cases, especially after infectious diseases, there may have been no previous hematoma present. After submucous resection a hematoma sometimes arises, which may become infected, and which should be treated after the manner about to be described.

Septal hematoma and abscess are both usually bilateral. If non-traumatic perichonditis occurs on

one side first, it soon perforates the cartilage and establishes itself on both sides of the septum.

The clinical findings are quite characteristic. By lifting the point of the nose one sees on both sides of the septum a mucous-membrane sac which is distinctly fluctuating. Constitutional symptoms in

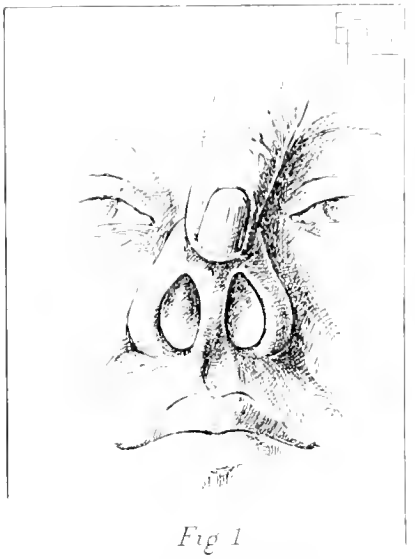

Fig 1

Fig. 1.—The pus-filled sac on each side of the septum causes complete occlusion of the nose.

both traumatic and non-traumatic types are sometimes quite severe. Slight pains and fever only may be present with nasal insufficiency and its results, such as headache, as the chief complaint; but

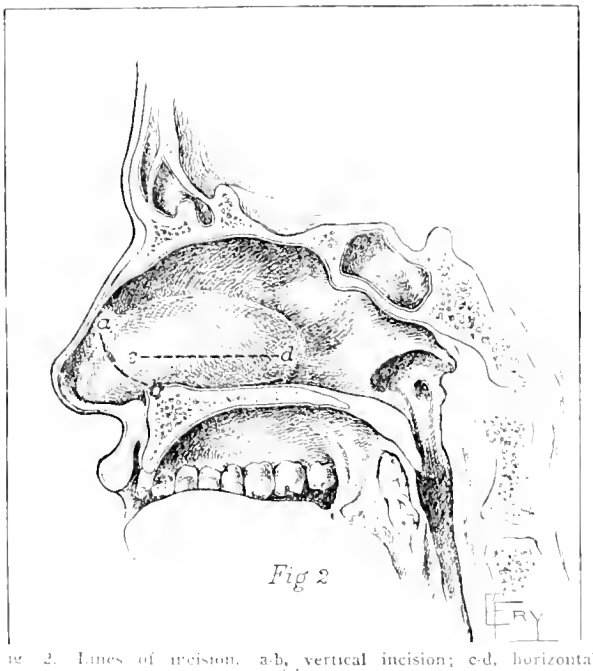

Fig 2

Fig. 2. Lines of incision. a-b, vertical incision; c-d, horizontal incisions.

in the course of infectious diseases, especially in influenza and erysipelas, severe constitutional symptoms are the rule. There is an initial chill. The temperature is high, rising even to 104° F., the patient experiences localized pains in the head and body, and in a short time there is complete nasal stenosis, which frequently, but not always, produces a reddening and swelling of the external nose. Meningitis or abscess in the anterior fossa of the skull may result by way of the anterior and posterior ethmoidal vessels.

Hematoma and abscess are quite similar in their external appearance, but the constitutional symptoms already mentioned always point to abscess. The differential diagnosis is, however, not very important, since the treatment is essentially the same, namely, prompt incision and drainage of the sac.

Treatment.—I have found the following method of treatment serviceable: A vertical incision is made on the left side of the septum at the junction of mucous membrane and skin and is carried directly across the floor of the nose. This is the same incision which I use in submucous resection of the septum. A second incision running near to and parallel with the floor of the nose is carried forward from the middle point of the vomer until it almost but not quite meets the first incision. The object of not joining the incisions is to prevent retraction of the flaps and a large amount of resultant scar tissue. The mucoperichondrium is then reflected and the entire abscess cavity is carefully curetted with flexible curettes until all pyogenic membrane and detritus are removed. The cavity is now irrigated with a dilute peroxide solution, followed by normal saline, and two drains are introduced. For this purpose I prefer wick gauze, which has been saturated in a 0.2 per cent. solution of formaldehyde in boric acid. The first drain is passed through the horizontal incision and is pushed far upward into the pocket. The second drain is introduced through the anterior incision to meet the first drain, but tight packing should be avoided. Finally a small strip of plain gauze is placed on each side of the septum for support.

There is absolutely no need of making an incision on each side of the septum. Moreover, retraction of the edges of the wound and the formation of granulations may result in perforation. Deformity of the external nose follows only when the entire bridge of cartilage along the internal dorsal aspect of the nose is also destroyed. The so-called "sinking in" of the tip of the nose, whether after operations or after injuries, will not take place if a strip of cartilage one-fourth inch wide remains still intact as a bisector of the angle between the two sides of the external nose. In an extremely late stage of the disease if the abscess has spontaneously ruptured, if the sac has collapsed, and if granulations have formed about the margin of the wound, the differential diagnosis between residual abscess, tuberculosis, and syphilis may be somewhat difficult. In such cases histological examination of the granulations and bacteriological examination of the secretions make the diagnosis clear. While abscess of the septum is not an unusual surgical condition, no mention is made of it in several of our best American books on diseases of the nose and throat. This method of treatment is, I believe, thoroughly surgical and will give very satisfactory results in all cases.

14 Central Park West.

Goodwill of Physician's Practice Is Property.—While some doubt has been expressed as to whether the matter of good will, as a property asset, can be applied to the practice of a physician or other professional man, the weight of authority is that the good will of a physician or other professional man is a property asset, subject to disposal, within the limits prescribed, and in the same manner as the good will of any other business, and a breach of the same incurs the same liabilities.—Maxwell vs. Sherman, Alabama Supreme Court, 55 So. 520.

MORE SLEEP!

ADVANCE in our knowledge of the metabolism of the brain, the cord, and the autonomic system makes ever more easy of understanding the far-reaching injury that comes to us from having too little sleep. Dolley's work, for example, on the osmotic relations of the nuclei and cytoplasm of nerve-cells, research concerned with the supply of the fatty-protein chromatin, and the more recent definition of the interdependence of euphoria, malaise, blood pressure, pulse rate, epinephrin, thyroidin, and the pituitary extract tend to make the reason for this harmful lack of sleep more plain, and so to appear more important. It rapidly becomes obvious that these relations between blood-chemistry and brain-metabolism are of the most fundamental kind. The whole world knows that fat people are most often good-natured above thin people; it remains for some "neuro-chemo-histologist" actually to prove that the brain-cells of the fat man contain a larger proportion of the lipoid protein on which the most perfect nutrition of the grey-matter depends, both in the brain and in the sympathetic. Book's well-known research on the development of motor skill has shown us recently with renewed assurance that progress in skill can take place only when the learner "feels good," and not at all on "off days" when the circulatory metabolism is probably in some way a little out of order.

The other, the external, aspect of this matter comes to us even more insistently from the statistics of the lunacy commissions and from reports of nerve-sanatoria. More nerve cells than is proper are somehow in default and the results reach far afield. One is inclined to think that even the divorce courts would be less overcrowded were these unrested brain-cells returned to their primitive, natural vigor. No homily on the pace that kills, however, nor eulogy on the simple life (though great the universal need of both) is contemplated here, but only a simple physiological enumeration of the conditions that keep too many of us Americans, thoughtlessly or by compulsion, from sleeping our proper physiological allowance. It is not so much a matter of life and death, although every physician must realize how very many lives are shortened by needless nerve-fatigue, not so much a quantitative affair or mortality statistics, as one of quality—the *satisfaction in living*. No moral philosopher can get behind or beneath this as the *summum bonum* of our mortal existence—we all seek it, and can by no hook nor crook help seeking it, as the forest trees seek the open sunlight above. That one, and perhaps the chief, cause of this qualitative defect, not measurable but none the less immeasurable, is too little sleep, the deficiency accumulating slowly year by year, becomes more and more obvious to those who best understand the delicacy and the complexity of the underlying bodily conditions.

Civilized man has lost his natural indicator for the need of sleep, namely, abundant muscular exercise pure and simple, unmarred by accompanying nerve-fatigue. We are apt eternally to forget that our brains were evolved as organs of motor coordination, and that, lacking this kind of exercise, their metabolism may be deranged. We are apt to call Towser and Tabby lazy animals, but no physiologist doubts that they live more hygienically in respect of sleep than do their human masters or mistresses, although many of these domestic pets, too, that are city-livers, get only a small fraction of the exercise they really require. But, like their wild brothers in the forest and on the plains, they sleep much and often. In the cities well-to-do multitudes live and die without experience of the "pure delight" of unadulterated muscle-fatigue and of the sudden and deep sleep that normally follows a day of purely muscular work. Here, then, is one reason why we sleep too little and too ill, save when, perhaps, in camp on our vacations in the wild. Should not these experiences teach us something?

Perhaps the second most efficient reason why we sleep too little is the general use of grey-matter stimulants—coffee, tea, cocoa, tobacco, alcohol, all or one or more in a day. Largely because at times they have enjoyed good sleep immediately after taking these, many unmedical persons are firmly convinced that they are not kept awake by these stimulants, when, in reality, as a rule they are. Of course, at times one may sleep in spite of them, for reasons that no one can as yet explain. More active bodily catabolism would rid the body more promptly of the alkaloids, etc., and so minimize their harm. As it is, throngs of sedentary people are kept from feeling normally sleepy at the proper time by these stimulants to the insistent association of ideas. Thus the physiological bedtime is ignored in favor of an artificial hour dictated by drugs more or less injurious, somnolently speaking.

A third reason obviously is the evening-entertainment habit, despite the necessity of early rising for work. How numerous are the theater-mad and the opera-mad and the bridge-mad in our day and generation needs no emphasis, and they unduly waste the sleep-time.

A last reason that may be recalled for our sleep deficiency is the vicious circle of nerve-cell exhaustion that makes sleep scanty and incomplete. The causes of this are both too trite and too numerous for proper discussion here, but among them are some that are underestimated. For example, the almost continual light- and sound-stimulation (rhythmic electric signs, milkmen, auto-horns, etc., etc.) to which dwellers of the large towns are now, day and night, subjected would wear out the strong-

est mechanism, while certainly the neurones are the most delicate of all known organs—unless it be the ear and the eye. Here we are victims of a negligence of physiological health which a later age will look back upon as only just removed by a few years from the renaissance of common sense.

Proper coordination by the nervous system underlies every other essential thing in the body and in the mind, if not in the spirit; its vigor, therefore, is of preeminent importance; its rest is conditioned by its sleep, adequate in quantity and in quality—and withal not unhappy.

THE PROFESSIONAL SECRET AND THE REPORTING OF VENEREAL DISEASES.

From its priestly origins before the dawn of recorded history, the obligation of secrecy has been handed down as one of the most sacred traditions of the medical profession. The utterances of Hippocrates and Charaka crystallized the sentiment of preceding centuries, and he who took the oath of keeping inviolably secret that which he might "see or hear amid the lives of men which ought not to be noised abroad" became amenable for the infraction of this oath, not only to the opprobrium of his colleagues but also to the penalty of the law of the land. But the obligation of secrecy has not remained an inflexible one; the complexities of modern life and the demands of public polity have, through the agency of legislative enactments and judicial interpretation, distinctly limited the extent and scope of this obligation. One of the momentous problems awaiting solution is that of reconciling the rights of the patient and those of the public in the modern warfare against venereal disease.

One of the recommendations made by the committee on the control of venereal diseases in its report to the section of Preventive Medicine at the 1911 meeting of the American Medical Association was that a law should be enacted requiring the reporting of all cases of venereal disease by physicians. In fact, California had already passed such a law. The city of Cleveland had also made venereal diseases reportable, and, although it was admitted that the strict enforcement of this statute was not possible, nevertheless the public health authorities had the power to order to a hospital anyone who was discovered with venereal disease and whose occupation rendered him or her a distinct menace to the public. In Chicago dispensaries and hospitals had been required to report all cases of venereal disease under treatment. In Detroit the Department of Health placarded houses of prostitution in which cases of venereal disease were discovered, and the diseased inmates were removed to a public hospital. If, however, the victim voluntarily reported herself, she was given the alternative of going to the hospital of her own accord, in which case the house was not quarantined. In a paper on the reportability of syphilis and gonorrhea, read by F. M. Greene at the above meeting, it was pointed out that Norway was the first European country to enact laws for the control of venereal disease; State care of the victims was provided for as early as 1774, but it was not until 1901 that the most stringent laws for this purpose were enacted. Sweden, Denmark, and Prussia at various times passed similar laws, in all of which it was left to the discretion of the private physician to report to the public authorities the names of individuals who neglected to take the proper precautions or to submit to proper treatment for venereal disease.

The one stumbling-block in the way of State control of this peril is the inviolability of the professional secret. The European nations that have undertaken the solution of this problem have recognized this difficulty and have met it half way by regarding the venereally diseased victim as waiving his privilege to the protection of this secrecy if he neglects to apply for proper treatment or to follow the instructions of his physician. In other words, the enlightened modern attitude with regard to the physician's obligation to his patient and the public is a rational one: the physician is bound to secrecy provided this does not militate against the welfare of the public. It would seem unwise, therefore, to enact inflexible laws compelling the notification of all cases of venereal disease. These laws would defeat their purpose for two reasons: physicians would fail to report their cases, which has been the experience in Cleveland, and the victims of venereal disease, fearing public exposure, would hesitate to apply for proper treatment.

That this problem is not a new one is shown in an excellent historical analysis of the respective obligations of the medical profession with regard to the preservation of secrecy and to the notification to public authorities of diseases menacing the public health. This analysis forms part of a volume that has recently appeared under the title "Professional Duties and Professional Questions, an Historical Study,"* by I. Fischer, Director of the Charité Gynecological Institute of Vienna. In discussing the evolution of the duties of medical practitioners with reference to the reporting of infectious diseases, this writer notes that the question of reporting venereal diseases arose as early as the end of the sixteenth century, when, in the city of Geneva, the followers of Calvin endeavored to make the capital of the Protestant world a model of order and morality. In 1590 the Consistory informed the municipal council that the surgeons of the city were treating cases of syphilis, which was accounted a public menace. The council commanded the surgeons to submit the names of these patients. To protest against this request, the surgeons appointed a committee of three, who appeared before the council and pointed out the obligations connected with the professional secret and the dire consequences, not only to the afflicted but also to their families, that would result from its violation. The council, apparently satisfied with this response, transmitted it to the Consistory. But eighteen years later a similar demand was made. The first physician who refused to obey this edict was thrown into prison. Frightened by this zeal of the public authorities, the remaining members of the profession at once sent in the names of their syphilitic patients. An amusing incident of this surrender

*"Aerztliche Standespflichten und Standesfragen, eine historische Studie," von Dr. I. Fischer. Price 4 marks. Vienna and Leipzig: Wilhelm Braumüller, 1912.

was the fact that one of these names was that of an individual who, both as a physician and as a municipal councillor, had taken part in this discussion. When, for the third time, in 1621, a repetition of the same demand for public notification was threatened, the practitioners of Geneva arose in one vehement protest: First, there was the oath of secrecy which they had taken on attaining their degree in medicine; Second, venereal patients, fearing public disgrace, would hide their affliction from medical men, which would be a greater public calamity than failure to report them to the authorities; Third, the disease in Geneva was not widespread, and there need not be any fear as to its dissemination.

It is the second of these arguments which may be advanced to-day with as much reason as it was nearly three hundred years ago.

CHILD NEUROPATHY AND THE FACIALIS PHENOMENON.

Child neurasthenia is now recognized as of common occurrence and of probably increasing incidence. Neurasthenia in adult life is often but a persistence of it. We also see in childhood evidences of marked neuropathy which may not have culminated in any overt symptom of actual neurasthenia. The latter state is chiefly recognized by the presence of night terrors, bed wetting, nervous anorexia migraine, nervous cough, etc.; but children may be intensely nervous, sensitive, excitable, irritable, restless, prone to habit spasms, and yet may show no actual evidences of nerve exhaustion. This type of child may perhaps be said to suffer rather from disorders of personality or disposition than from actual neurasthenia, and certain neurologists are at present in favor of separating anomalies of personality from all other psychoneuroses, if for no other reason than the relative impotence of therapeutic measures in this class. It is best, perhaps, to limit the expression child neurasthenia to the more objective phenomena, and it is quite conceivable that such neurasthenics need not present marked alterations in disposition.

At a recent meeting of the Royal Imperial Society of Physicians of Vienna (*Berliner klinische Wochenschrift*, November 6) Hochsinger reported the results of an attempt at finding a simple criterion of the neuropathic constitution. He tested one hundred and seventeen children for Chvostek's sign, and obtained it in one hundred and one. Aside from children with the evidences of neurasthenia indicated above, the material included epilepsy, hereditary syphilis, Mongolian idiots, myxedematous children, and excitable idiots. The age limits were four and twelve years. The symptom in question was comprehended as a sudden twitching of the lip and cheek muscles upon percussion over branches of the facial nerve. This symptom was present in a very large percentage of each type of child investigated, although in but three out of eight epileptics. It was found that many of these children had been under treatment during the nursling period for eclampsia or other evidences of spasmophilia, and that Chvostek's sign had also been obtained at this period. Hochsinger was also able to test many of the mothers and obtained the sign in 60 per cent. of these. He also found that while in male children the phenomenon could not as a rule be induced after the age of fifteen, it persisted indefinitely in girls, sometimes even to the menopause. The fathers of these children seldom showed evidences of neuropathy. He differs with Chvostek as to the thyroid or parathyroid origin of the phenomenon.

Typhoid Fever in the Philippines.

Major Weston P. Chamberlain, United States Army Medical Corps, discusses in the *Philippine Journal of Science*, October, 1911, typhoid fever in the Philippine Islands. In the first instance, this comprehensive article shows that typhoid fever is a widely scatered and common disease in the Philippines; its incidence in Manila is above the average rate for the United States, and is exceeded only by a few American cities. The average admission rate among American soldiers in the Philippines exceeds that for troops serving in the United States, while medical officers from many regions report the frequent occurrence of typhoid fever among the Filipinos. Statistics from the latter, however, show a much lower typhoid rate than among white troops, possibly due to failure to diagnose the atypical cases. Many epidemics have occurred among soldiers in the Philippines, and three outbreaks among natives have been studied. Only one typhoid bacillus carrier, so far as the author is aware, has been found in the Philippines. It is even more curious to have to record on the authority of Chamberlain that paratyphoid fever is seldom met with in the Philippines, so rarely indeed that it is stated that only two or three undoubted cases of paratyphoid infections have been encountered. In India, on the other hand, in which, in parts at least, the conditions resemble those of the Philippines, paratyphoid fever is, according to officers of the British Army Medical Service, by no means uncommon. In fact, recently several army medical officers in India have reported many cases of infection by *Bacillus typhosus A*. Although the morbidity is so high, the mortality for white troops in the Philippine Islands during the past five years has been no higher than at home. It appears somewhat higher for Filipinos, but this may be due to failure to diagnose all the mild cases. More than a third of the cases of enteric fever, whether among Americans or Filipinos, are entirely atypical and cannot be diagnosed without laboratory methods. Very valuable work is being done in different parts of the world in regard to typhoid fever, and especially with respect to the differentiation of the paratyphoid infections. This question is looming somewhat large, and therefore all investigations bearing on the subject are instructive and valuable, and in this light it is interesting to learn that such infections appear to be rare in the Philippines.

Starvation of Cancerous Tissue by Adrenalin Injections.

The starvation principle in the management of cancer, chiefly of the inoperable type, is an old resource as an accessory or palliative, and has been employed by Dawbarn and others with some success as the principal treatment of cancer of the head and face by ligating or occluding the main arterial branches leading to the growth area.

Parenchymatous injections of adrenalin for cancer were attempted originally by Reicher. At a recent meeting of the Laryngological Society of Berlin (*Berliner klinische Wochenschrift*, November 20) there was a demonstration by Holscher of a patient with an inoperable cancer of the tongue which had progressed so far as to demand tracheotomy—in which the Reicher method had produced brilliant results. The cancerous lymphatic metastases had previously been extirpated. The effect of the injections was the prompt production of necrosis. Tissue came away in pieces of any size up to that of a hazel nut. The ultimate result was a necrosis of the entire tumor mass *in loco*. With the fear of hemorrhage no longer present the author did not wait for the remainder of the mass to slough, but extirpated it with the cold snare. The injections were not discontinued, but were made from time to time in the cicatricial area. The patient's health improved notably. At present there is evidence that small recurrent nodules are undergoing necrosis. Schoetz stated that he had had a similar case in which Reicher's method was used without benefit and with probable injury; since the suppuration of the cancerous mass could be attributed to it. Gräffner saw benefit follow a single injection, evidently made as a test. Rosenberg was obliged to discontinue adrenalin injections because of the pain caused. Hölscher, in response to inquiries as to technique, stated that he began by giving four or five drops of adrenalin in a local anesthetic solution, increasing the dose of adrenalin gradually and diminishing the bulk of the fluid at the same rate. He had never seen pain follow, or any other unwished for symptom. The injections should be deep. In his case fragments were coughed out or dislodged by the aid of swallowing. The snare went through the necrotic tissue like butter. Hemorrhage never occurred.

Biochemical Rationale of Menstruation.

At the present time biochemistry is made to account for a vast number of normal and pathological phenomena, often no doubt to the unjust exclusion of other elements—although biophysics may perhaps be included under what we term biochemistry for the sake of simplicity. There would then remain unclassified and unknown biological phenomena hitherto conceivable under vital processes—a term now become so obscure as to be seldom employed outside of controversies. At a recent meeting of the Munich Gynecological Society (*Münchener medizinische Wochenschrift*, November 21) Klein advanced the following biochemical doctrine of the nature of menstruation. Three inner secretions of the ovary—folliculin, ovulin, lutein—which jointly make up oophorin, render the uterine mucosa capable of transforming the circulating maternal blood into trophema or nutrient blood, intended for the reception of the expected impregnated ovum. Should the latter not arrive the blood escapes as menstrual blood. Both trophema and menstrual blood refuse to coagulate. Dysmenorrhea membranacea may be explained as the result of an autolysis of the spongy layer of the uterine mucosa. Painful menstruation may be accounted for as due to the failure of the ovarian hormone to produce noncoagulability of the blood, which, clotting *in utero*, requires expulsion. The same insufficiency of hormone production may explain scanty menstruation. Conversely, menorrhagia may be explained by overaction of the ovary. The explanation of the menopause and of the results of castration is sufficiently obvious.

News of the Week.

Dr. Doty Awarded Medal for Health Work.—The American Museum of Safety at its annual exercises in the Engineering Societies Building on January 18 awarded three gold medals for the greatest achievements of the last year in safeguarding life and limb in American Industries and promoting safety and sanitation in daily and industrial life. The *Scientific American* gave the first medal for the most efficient safety device invented in the last three years. This was awarded to the Norton Company of Worcester, Mass., for safety devices employed in its manufacture of grinding machinery and emery wheels. The Travelers' Insurance Company of Hartford, Conn., presented the second gold medal for the employer who did most for the protection of the lives and limbs of his employees by means of safety devices, which was awarded to the Pennsylvania Railroad. The third gold medal was presented by Dr. Louis Livingston Seaman "for progress and achievement in the promotion of hygiene and sanitation, and the mitigation of occupational diseases" and awarded to Dr. Alvah H. Doty. Prof. F. R. Hutton, who made the presentation, said that the award was made to Dr. Doty as the man who had achieved more than any other in securing the public health and preventing disease and providing safety for us, our industries, our homes, and our children. In the absence of Dr. Doty the medal was accepted for him by Dr. John W. Brannan. The American Museum of Safety proposes to erect a new building at a cost of $1,000,000, for which an appeal will soon be made to the city and State government.

The Meningitis Situation in Texas.—Dr. Ralph Steiner, president of the State Board of Health, expresses the opinion that the epidemic of meningitis in that State is well in hand. At a meeting of the State Board of Health on January 10 resolutions were passed by that body advising the closing of public schools, discouraging public gatherings, and advising the closing of places of amusement upon the appearance of meningitis in any community, at the discretion of the local authorities. A resolution was also passed complimenting the Dallas Board of Health on the manner in which the epidemic was handled in that city. It was also resolved that the president of the State Board of Health be authorized to use every effort to secure a supply of the approved New York Board of Health serum for distribution throughout the State. Owing to the prevalence of the disease among the colored population, local health authorities were advised to endeavor to secure the cooperation of colored physicians. It was urged upon county attorneys that, owing to the importance of early diagnosis and immediate use of the serum, it was their duty to prosecute all unauthorized persons prescribing for sick people and those delaying a proper diagnosis and treatment, as such delays tended to spread the disease and to increase its fatality. Dr. Sophian of the Health Department of New York City, who went to Dallas to assist in controlling the epidemic, expects to remain as long as his services are so urgently needed. The quarantine against Texas, which was put into effect by the Mayor of Shreveport, La., was abolished by

the Board of Health of that city, having been informed by Dr. Dowling, president of the Louisiana State Board of Health, that the right to enforce quarantine rested with the City Council and not with the Mayor. Dr. Dowling appointed a physician to register and record all Texans who entered Shreveport until further developments in the epidemic.

Yellow Fever on the "Yorktown."—According to a cablegram received at the Navy Department, Commander Levi C. Bertolette, commanding the American gunboat *Yorktown*, which has been protecting American interests in Equador, has died from yellow fever.

The Death Rate in New Orleans.—The death rate of New Orleans for the year 1911, with non-residents excluded, was 13.88 per 1,000 population for the whites and 24.50 for the negroes, making the average rate 16.78. The reporting of whooping-cough has been made compulsory owing to the unusually high death rate from that affection, there having been 112 deaths caused by it in 1911 against 17 for the previous year. The total number of deaths from all causes was 195 less than in 1910.

Death Among Doctors.—During the year 1911 there were 2,145 deaths among physicians in the United States and Canada, or, reckoning on an estimate of 140,000 physicians, the rate was 15.32 per 1,000. For the nine previous years the death rates were as follows: 1910, 16.96; 1909, 16.2; 1908, 17.39; 1907, 16.01; 1906, 17.0; 1905, 16.36; 1904, 17.14; 1903, 13.7, and 1902, 14.74. The average annual mortality was 16.11 per 1,000. The age of death varied from 23 to 99, with an average of 59 years and 10 months. The chief causes of death in the order named were: Cerebral hemorrhage, "heart disease," senility, pneumonia, external causes, and kidney disease.

Physical Conditions at the Quarantine Station.—The annual report of Dr. Alvah H. Doty, Health Officer of the Port of New York, points out that the buildings on Hoffman Island and part of the buildings on Swinburne Island have been built for many years and are badly in need of reconstruction. He suggests that a legislative committee be appointed to inspect the quarantine establishment with the view of ascertaining the appropriation required. The report states that the big work of examining all immigrants from cholera infected ports has resulted in an increase of at least 100 per cent. in the efficiency of the laboratory, but the report states that the condition of the laboratory is very cramped and should be brought to the attention of the Legislature.

To Isolate Pupils Having Trachoma.—It is admitted by the health authorities in New York that grappling with trachoma in clinics and dispensaries has failed to limit the spread of this disease and consequently a new plan is to be tried. At the suggestion of Dr. William H. Park, pupils having trachoma will be in one room in a building separate from the public school, if possible. The plan is to be tried at Public School No. 21, which is located in a district composed largely of those who have lately arrived in this country. A room has also been set apart in this school where children suffering from this affection will be treated by an ophthalmologist from the Health Department. It is said that there are no more children now with sore eyes than there have been for many years, but it is thought that the disease can be stamped out if proper measures are adopted.

To Open More Milk Stations.—It is announced that the Health Department of New York City will open twenty-eight additional milk stations and that all will be in operation by February 1. The Health Department will then have fifty-five stations in the different boroughs.

High Record for Operations.—It is reported that a young woman, twenty years of age, has just been discharged from the Medico-Chirurgical Hospital of Philadelphia after having undergone thirty-two surgical operations in seven years. She entered the hospital to have a deformity of the leg corrected which took six operations; when about to leave the hospital she was attacked with appendicitis and it required twenty-five operations to correct aftermaths of this first appendicitis operation.

The Vaccination Fight in East Orange, N. J.—Trouble between the Board of Education of East Orange and the anti-vaccinationists began about a year ago when an order was issued requiring all children attending the public schools to be vaccinated. In order to evade the order of the Board of Education scars were made in some instances by applying a fluid preparation and in others old scars were shown until recently when these ruses were discovered. On January 18 notices were sent to parents announcing that children who were out of school because their parents would not permit them to be vaccinated would be treated like ordinary truants. The anti-vaccinationists are well organized and provided with funds with which to fight the school board.

Medical Examiners Sever Reciprocal Relations.—The Iowa Board of Medical Examiners at their meeting on January 12 severed reciprocal relations with Illinois and hereafter will refuse to recognize the certificates granted by Illinois.

Urges State License for Physical Culturists.—Dr. E. W. White, physical instructor in the Illinois Athletic Club, who believes that physical training under the direction of an incompetent instructor often does more harm than good, is endeavoring to have a law passed requiring this class of instructors to pass an examination by a civic board in order to obtain a license before being permitted to follow their profession.

A Tax for Physicians.—A bill is pending in the Mississippi Legislature which imposes a privilege tax of $10 on practising physicians.

Dr. Wiley.—The Congressional committee appointed to investigate the charges against Dr. Wiley has found that the accusation of conspiracy has not been established, but that the accused officials were actuated solely by a desire to procure for the Bureau of Chemistry an efficient assistant in the person of Dr. H. H. Rusby, under terms and conditions which these officials believe to be in entire accord with the law. The report declares that Dr. Wiley and his associates communicated the fact of Dr. Rusby's employment to Secretary Wilson. It holds, however, that the contract is technically illegal and recommends that Congress make specific provision for the employment of experts in the Department of Agriculture.

How the Country was Saved from an Invasion of Cholera.—In the recently issued monthly bulletin of the New York State Department of Health there is a brief history in the form of a report of "How Cholera Was Kept Out of New York State." It tells of the fight waged by Dr. Alvah H. Doty and the State Department of Health from July 20 to November 10, when the

special work at Quarantine closed. In the four months seventy-seven steamships arrived from affected ports with 26,455 passengers who were examined to determine whether or not they were cholera bacilli carriers. Of these 150 were detained for further examination and of these twenty-six were proved to have cholera or to be carriers. No cases of cholera were discovered after August 18. All the time the Health Officer with his efficient staff was working day and night to ward off the threatening invasion of cholera, the Governor of the State, through his agent from Oswego, Mr. Bulger, was persecuting him and accusing him of incompetence and worse. The Governor is finding it very difficult to get a competent man to replace Dr. Doty.

Dr. Frederick Cheever Shattuck of Boston, Mass., has tendered his resignation as professor of Clinical Medicine in the Harvard Medical School, to take effect September 1, 1912. Dr. Shattuck has been made Professor Emeritus, in the chair which he has held since 1888. He has been an instructor in the school for over thirty-two years.

Dr. P. H. Eijkman, Chairman of the Rontgen Ray Society of the Netherlands, arrived in New York on January 17. The object of his visit to this country is to promote "internationalism," by which term he means international organization with regard to scientific bodies.

Prof. J. George Adami has decided not to accept the chair offered him at the Northwestern University, Chicago, and will remain at McGill University.

Dr. Richard C. Cabot was elected president of the Mount Sinai Hospital, Boston, on January 11.

Dr. Edward H. Bradford has sent in his resignation as surgeon to the Children's Hospital of Boston, to take effect on June 1.

Fire Destroys Hospital.—The main building of the Maternity Hospital of the New England Reform Society, located at Jamaica Plains, Mass., was destroyed by fire on January 17. The building was new and the loss is estimated at $25,000.

New Device for Mount Sinai Hospital.—The Directors of Mount Sinai Hospital have decided to install refrigerating apparatus for the purpose of cooling certain wards during the summer months. While this plan has been tried in army hospitals and in the Philippines in the treatment of tropical diseases, it is new in general hospital work. As the work is experimental, only small wards will be cooled where heart and intestinal diseases will be treated.

Hospital for Cedar Falls, Ia.—Plans have been adopted for the construction of an emergency hospital to cost $5,000, in connection with the State Teacher's College at Cedar Falls.

Hospital for Santa Rosa, Cal.—The Providence Sisters plan to build a $75,000 hospital which will serve to minister not only to the people of Santa Rosa but to the surrounding counties. The city will present the site for the hospital building.

For Charity.—At the meeting of the directors of the Tuberculosis Preventorium for Children at Farmingdale, N. J., on January 16, it was announced that $115,000 of the $150,000 endowment fund which it is proposed to raise was in hand. It was then announced that John D. Rockefeller and Andrew Carnegie had each promised $10,000, leaving only $15,000 to be raised. It was suggested that churches and other organizations be asked to complete this sum. With the buildings made possible by this fund 172 children can be cared for at one time, or about 600 a year. The will of Henry Batterman of Brooklyn leaves the income of $20,000 to the Bushwick and East Brooklyn Dispensaries and to the following institutions $5,000 each; The Brooklyn Home for Consumptives, the Brooklyn Association for Improving the Condition of the Poor, the German Hospital, and the Brooklyn Hospital. By the will of Mrs. Emily Howe Hitchcock the Hitchcock Memorial Hospital, at Hanover, N. H., which bears the name of the testatrix, receives $20,000. The will of Mrs. Clara E. Wellman of Brookline, Mass., bequeaths to the following charities $1,000 each: Vincent Memorial Hospital, Boston Nursery for Blind Babies, Home for Crippled Children, and the Massachusetts Homeopathic Hospital.

New Medical College for Hungary.—The Minister of Education has laid before the Hungarian Parliament a bill stipulating the erection of two new universities in Hungary in the cities of Pressburg and Debreczin. Only the Pressburg institution will include a medical school. Owing to its large hospital, children's hospital, school for midwives, this city is especially suitable for a medical school and the government will grant $400,000 annually for the next ten years for the development of this institution.

Bill to Stop Gifts to State Medical Examiners.—An act to prevent medical examiners from accepting gifts from public service corporations, manufacturing concerns, and accident insurance companies has been introduced into the Rhode Island House of Representatives. The act provides a penalty of $100 for any violation of its provisions, and also provides for the removal of any medical examiner from his office who may be found guilty of accepting such gifts.

Utah State Board to Enforce Medical Laws.—At its meeting on January 4 the Utah Board of Medical Examiners adopted measures whereby every violator of the medical laws of the State is to be brought to account and either convicted or driven from the State. Arrangements were also completed at this meeting with the Idaho Board of Examiners for reciprocal relations between the two States whereby the granting and honoring of licenses will be placed on a uniform basis.

A New Boston Hospital.—It is announced that the new hospital for children and the nurses' home are about completed and the formal opening will be held on February 7, when Dr. Abraham Jacobi of New York and President A. Lawrence Lowell of Harvard will be the principal speakers.

The New Haven (Conn.) Medical Association at the annual meeting, January 18, 1912, elected the following officers: *President*, Dr. Norton R. Hotchkiss; *First Vice-President*, Dr. Stephen J. Maher; *Second Vice-President*, Dr. William F. Verdi; *Secretary*, Dr. Robert G. Tracy; *Treasurer*, Dr. Thomas V. Hynes; *Executive Committee*, Drs. Ralph A. McDonnell, John F. Luby, and the president; *Library Committee*, Drs. Gustavus Eliot, Wilder Tileston, and the second vice-president; *Finance Committee*, Drs. Frank H. Wheeler, Robert E. Peck, and the treasurer; *Literary Committee*, Dr. Charles D. Phelps, the first vice-president, and the secretary. The association has 137 members, 5 associate members, and 16 non-resident members. During the year twenty meetings were held, with an average attendance of forty-two. The building fund in the hands of the finance committee amounts to $15,000, including a legacy of $3,000 recently received from

the estate of Dr. Samuel D. Gilbert. The library contains 1,000 bound volumes of periodicals and about 5,000 books.

The New York Physicians' Mutual Aid Association held its forty-fifth annual meeting on January 10 at the Academy of Medicine, and elected the following officers: *President*, Dr. William F. Muttendorf; *Vice-Presidents*, Drs. Wendell C. Phillips and James W. Ingalls; *Recording Secretary*, Dr. A. Edward Davis; *Assistant Secretary*, Dr. Edward S. Peck; *Corresponding Secretary*, Dr. W. B. Jennings; *Treasurer*, Dr. Daniel Lewis; *Directors*, to serve from 1912-1915, Drs. W. H. Katzenbach, H. J. Boldt, and W. B. Hoag. The mutual Aid Association is in a successful condition. It carries an insurance of $1,000, at an annual expense of from $16 to $20. The president's report stated that the capital fund is $78,000; and the membership comprises more than 2,100 physicians.

Philadelphia County Medical Society.—At the annual meeting held January 17 the following officers were elected for the ensuing year: *President*, Dr. Levi J. Hammond; *Vice-President*, Dr. J. Torrance Rugh; *Associate Vice-Presidents*, Drs. Wilmer Krusen, Stewart C. Runkle, George H. Nofer, S. A. Lowenburg, and I. Pearson Willits; *Secretary*, Dr. Wm. S. Wray; *Assistant Secretary*, Dr. Howard Childs Carpenter; *Trasurer*, Dr. Collier L. Bower; *Censor*, Dr. C. A. E. Codman; *Directors*, Drs. Wm. S. Newcomet, J. Torrance Rugh, and Wm. Duffield Robinson.

Continuance of Training Schools for Nurses.—At a meeting of the executive committee of the Hospital Conference of the City of New York, held January 12, the following resolution was adopted: "That the president be authorized to appoint a committee of five who shall act with the president to secure (*a*) either such modification of the Nurse Practice Act or of the regulations adopted by the Education Department under the said act; or (*b*) such interpretation by the Education Department of the existing regulations as shall render it possible for the hospitals of the city to continue the training of nurses in sufficient numbers to meet the public demand for trained nursing service. The president appointed the following named committee: Dr. C. Irving Fisher, Dr. Thomas Howell, Dr. S. S. Coldwater, Rev. A. S. Kavanagh, Dr. F. A. Brush, Rev. Geo. F. Clover.

Anatomist Wanted in Army Medical Museum.—The United States Civil Service Commission announces that an examination will be held on February 20, 1912, to secure eligibles from which to fill a vacancy in the position of anatomist in the Army Medical Museum. Information regarding applications and places of examination may be had by writing to the United States Civil Service Commission, Washington, D. C.

The Cost of Public Health.—Dr. William E. Park, Commissioner of Health of Rockford, Ill., has been gathering statistics to ascertain what it costs to promote health in various American cities. He finds that some of our cities spend only 5 cents per person on health, while others spend as much as 93 cents per inhabitant. The average for cities having more than 300,000 population is 32.8 cents per capita. He finds that the death rate is not always in keeping with the amount spent. This means that the money is not always efficiently spent. He believes that cities of over 300,000 population should spend at least a dollar per capita, while those of less than 50,000 should spend at least 50 cents per inhabitant. He also finds that European cities spend more money per capita on health than we do, and that they invariably find that it pays.

Physicians Refuse Contract Work.—The physicians of Westfield, Mass., met on December 29 and formed an organization to be known as the Westfield Medical Society. They agreed that no members should perform lodge or contract work, except as town physician or school inspector. The Lee County Medical Society of Louisiana has also passed resolutions expressing disapproval of lodge and contract work.

Destroy $80,000 Worth of Opium.—Under the direction of the Collector of Customs of San Francisco, 3,000 five-tael tins of opium, valued at $80,000, have been seized and destroyed since June, 1911. It is estimated that, while the International agreements are being satisfied, the United States Government is losing $2,000,000 in revenue annually.

Obituary Notes.—Dr. Perry Hall Dudley died in Philadelphia on January 17 at the age of 42 years. He was graduated from the Hahnemann Medical College of Philadelphia in 1892. He was at one time resident physician in the Children's Homeopathic Hospital and later of the West Philadelphia Homeopathic Hospital.

Dr. I. H. Nichols of Stamford, Vt., a graduate of Albany Medical College, died at his home December 30, at the age of 68.

Dr. John F. Davis of Brooklyn, N. Y., a graduate of Bellevue Hospital Medical College, New York, in 1874, died at his home December 31, at the age of 60 years. He was a member of the King's County Medical Society.

Dr. James Allen of Ogden, Utah, a graduate of Washington University, Medical Department, St. Louis, Mo., in 1867, died at his home December 27. He was 81 years old. He was a Thirty-Second Degree Mason and served in the Union Army. He was medical director of the G. A. R. and at one time post commander.

Dr. Samuel Green Sewall of New York City, a graduate of Dartmouth in 1844, a retired physician, died at his home December 29, at the age of 88 years.

Dr. Hugh P. Roden of Newark, N. J., a graduate of the Missouri Medical College, St. Louis, died of pneumonia at his home December 31, at the age of 67 years.

Dr. William Constantine Pise Boone of Plainfield, N. J., a graduate of the University of Maryland, School of Medicine, in 1872, died at the Johns Hopkins Hospital, Baltimore, Md., December 30, at the age of 67 years.

Dr. Edward Hubbard Welch of Winsted, Conn., a graduate of Yale Medical School, New Haven, Conn., died of paralysis at his home December 28, at the age of 60 years.

Dr. Henry Lewin of New York City, a graduate of the New York Electric College in 1896, died at his home December 28.

Dr. Chauncey C. Turner died of cerebral hemorrhage at Wilkesbarre, Pa., on December 30. He was graduated from Jefferson Medical College in the class of 1909. He was for six months resident physician in the Children's Hospital of Philadelphia.

Dr. William H. Senderling died at Philadelphia on December 30, at the age of 64 years. He was graduated from Jefferson Medical College in the class of 1869.

Correspondence.

CHRISTIAN SCIENCE IN THE PANAMA ZONE.

To the Editor of the Medical Record:

Sir:—By decree of the President of the United States the Christian Science healer is made a doctor of medicine, if not "in name," certainly and what is far better for these sanctimonious seekers after the shekels, "in game." The following regulation has been issued for the medical government of the Canal Zone: "Any person shall be regarded as practising medicine within the meaning of this order who shall prescribe for, operate on, or in any wise attempt to heal, cure, or alleviate, or shall in any wise treat any disease or any physical or mental ailment of another, provided that nothing in this order shall be construed to prohibit the practice of religious tenets of any church in the ministration to the sick or suffering by mental or spiritual means without the use of any drug or material remedy, whether gratuitonsly or for compensation, provided that sanitary laws, orders, rules, and regulations as are now or hereafter may be in force in the Canal Zone are complied with." Is not this order a glaring example of the saying, "Republics are ungrateful"? Is it not an insult to the medical profession, members of which have sacrificed their lives to make the Canal Zone habitable and without whose aid Panama would have remained a tropical den of death? Was there ever such utter disregard of justice and propriety? That the administration deeply feels the criticism made upon it on this subject in the New York *Sun* of the 14th instant is evident from the fact that the Secretary of War himself has replied to it. Since I am the author of this criticism, I beg to call the attention of my colleagues whom the matter may have escaped to the facts here stated and to urge upon them to start a movement to induce the Canal Zone administration to rescind this disgraceful order.

In that criticism I wrote: "It is not my purpose to discuss the merits of this latest medical cult; the history of medicine abounds in the rise and fall of factions. Most of the latter may be reconciled on the ground that, as the great Hufeland has said, 'nature, not the doctor, cures.' Every individual who has been properly educated in anatomy, physiology, and pathology is cognizant of the truth that the physician is but the intelligent utilizer of the healing powers of nature—the *vis medicatrix naturæ*—which the father of medicine, Hippocrates, discovered and taught 2,200 years ago. . . . A man may in theory and even in practice be an allopath, a homeopath, or an osteopath; if he has satisfied the authorities of the State that he is entitled to a license to practise no one may gainsay it." How does the great lawyer and Secretary of War answer my query whether "the public should not at least be protected against contagion and infection from unreported and unguarded diseases?" "Most decidedly," he writes, "and the order of the President carefully secures such protection. Obedience to sanitary rules is exacted at the pain of criminal prosecution of every practitioner, whether medical or Christian Science." Was there ever a more flagrant *reductio ad absurdum?* How the Science healer is to make a diagnosis of a disease which he does not recognize as an entity does not trouble the honorable Secretary of War. How, even if he were by reason of profit willing to stultify himself, he is to know the difference between smallpox and acne, between diphtheria and tonsillitis, between scarlatina and erythema, does not seem to occur to him. And last, but not least, how the healer is to report a case of contagious disease which he does not see at all when he gives "absent treatment" does not seem to cause the great lawyer one single qualm. He, in fact, offers a premium for deceit and hypocrisy to those healers who are mercenary and to their credit be it said I believe that the Christian Scientists are not all in that category.

Pardonable as the War Secretary may be for having overlooked these trifles, he cannot escape criticism when he states in defense of his extraordinary legalization of Christian Science practice that "the recent order, which in effect exempted reputable Christian Science practitioners from the necessity of being licensed, merely followed the legislation of a large and important number of States." I am informed by Dr. Wisner R. Townsend, secretary of the Medical Society of the State of New York, that this "large number" consists of Connecticut, Maine, New Hampshire, South Dakota, and Tennessee, viz., five out of forty-eight States. The "importance" of these five States in population admits of discussion when comparison is made with the remaining States. Since I have not access to the census figures I can only say that I cannot subscribe to the view that they are either a large or an important number. The United States Government has always been conspicuous in the requirement of high ability, thorough training, and character of its appointees in the medical service, with the result that the achievements of the medical officers of this Government have redounded to its fame at home and abroad. The marvelous work of Dr. Gorgas in the Canal Zone is a shining example. What would the Canal Zone be to-day without his intelligent application of the principles which Lazear and Carroll died to establish?

By this "order" for the medical control of the Zone the United States Government has brought discredit upon itself because it confers with the stroke of a pen upon any man or woman who professes "Christian Science" all the rights and privileges of the physician, rights which are strictly guarded elsewhere by our Government with examination into the fitness of appointees and which all governments sedulously guard in the same manner. Why this enlargement of the privileges of this cult, why this addition to the laws of New York, 1910, chapter 659, section 173, which says, "this article shall not be construed to affect . . . the practice of the religious tenets of any church." I am informed that this section was inserted in order to protect the men practising circumcision as a religious rite against prosecution. Now comes the Canal Government and distinctly and specifically *adds* to the words religious tenets "*in the ministration of the sick and suffering by mental or spiritual means whether gratuitously or for compensation.*" In the New York law the last words are not found. A case is now on appeal in which a judge decided very properly that "the Christian Scientist has the right to believe that he can heal by prayer, but if he carries and puts this belief into practice for hire then he exceeds his rights." It remained for the Canal Zone Government to gratify the Christian Science people by absolving them even of "following the meek and lowly Jesus" who "went about doing good" without "compensation," and to place these

faithless followers of Christ on the same footing with physicians who have spent years in preparation for their calling. Will medical men supinely tolerate such encroachment upon their rights and upon the rights of the sick which it is their solemn duty to guard?

In conclusion I want to exonerate myself from the charge of disrespect to the government of the Canal Zone, for I have the deepest sense of obligation to and the highest regard for a President who stands out to-day amid the turmoil and contention of politics—*chevalier sans peur et sans reproche*—a man against whose integrity and patriotism no man dare breathe a suspicion. The above is written under a deep sense of injury to a calling to which I have devoted my whole life and from which I expect neither favor nor financial reward.

SIMON BARUCH, M.D.

51 WEST SEVENTIETH STREET, NEW YORK.

MULTIPLE HEREDITARY TELANGIECTASIS OF THE TONGUE, TURBINATES, AND SEPTUM WITH RECURRING HEMORRHAGES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Since the publication of my communication with the above title in the issue of January 20, 1912, I have been advised by Dr. Frederic M. Hanes, Department of Pathology, Columbia University, of his contribution to this subject, which appeared in The Johns Hopkins Bulletin, Vol. XX, No. 216, 1909. Having supposed Osler's paper in the *Quarterly Journal of Medicine*, 1907-08, to be the most recent résumé of this subject, I must confess to a certain laxity in my examination of the more recent literature. Hence the omission of Dr. Hanes' report of "Two Unrelated Families." Apology is herewith made for the omission of this and any other references which may possibly have escaped my notice.

CORNELIUS DOREMUS VAN WAGENER, M.D.

NEW YORK.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE AND THE MEDICAL PROFESSION—TUBERCULOSIS NOTIFIABLE—OSTEOARTHRITIS—TYPHOID OUTBREAKS—NEW YEAR HONORS—OBITUARY.

LONDON, January 5, 1912.

INSURANCE, in some aspect or other, is the absorbing topic of the day in all classes. Whatever may be the subject of conversation, this is sure to intrude, and the new act gives rise to a degree of excitement greater than that aroused when it was only a bill. The politicians are, as usual, divided, but the rampant socialism preached by its author in Wales this week has shocked not a few of his supporters and the extreme radical press is annoyed at the admissions he made. In the profession the differences of opinion have been somewhat more emphasized, but on the whole there remains greater unanimity in our ranks than our oldest members can recall.

The position of the B. M. A.'s Council remains rather equivocal. The great majority of them have been elected for other than political views, and, if they resigned, would no doubt be re-elected should they be willing to serve. It is the inner clique which gives dissatisfaction. Unhappily, the Association has for years been guided and controlled by an inner clique and the constitution seems almost as if contrived to facilitate this. But it must be said that the apathy or want of consideration of the other members contributes to the result—and something like it is to be seen in innumerable committees and journeying bodies of various corporations.

Sir James Barr, who is president-elect, has been opposed to the bill from its first proposal, regarding it as a fraud on the public, and has stated his reasons at length in the *Times* and other papers. But he has been reluctant, perhaps, until obliged to put himself, as it were, in opposition to the Council. On the question of resignation he said to our interviewer he meant to stick to his post until he had made the annual meeting in Liverpool a success—a very natural resolution in his peculiar position, for the arrangements must be already advanced. He admitted at the same time that if a vote of want of confidence were passed he supposed members of the Council would go to their constituents. Like many others of consultant rank, Sir James has no personal interest, but is concerned for the future of the profession and asks wiseacres to determine how that can be benefited by the act. Some of the radical papers, instead of attempting to meet his arguments, reprove him for speaking contemptuously of the Chancellor and his policy, but in doing so they use far stronger language to express their own opinions. Sir James Barr in some of his communications discourses on the importance of insurance of various kinds to the public, and shows the difference as to sick insurance between "selected" lives and those of the general population. But I can only refer to medical points. He shows that the Act as it stands "spells ruin" to numerous practitioners, and he denounces other evils which his Council do not appear to have foreseen.

Dr. Edwin Smith, who is a barrister-at-law as well as M.D., has shed much light on the doings of the inner clique and stated that the Council appeared to hold a brief for the Government.

The *Times*, which has published several articles appreciative of the profession, printed on Wednesday a most important letter from Sir Clifford Allbutt on the public interest in the present crisis and how that has been ignored by the Act, while history and reason demand as the solution "no contract but payment for work done on a standard tariff."

The London mass meeting organized by Dr. Fred. J. Smith has led to the formation of a "reform committee" of the B. M. A., which is to have its sub-committees in the branches. To-day circulars are going round accompanied by reprints of Dr. Smith's letter in the *Times* and calling meetings to push the scheme. It is not to destroy the Association but to reform it. "Stick to it," he says, as "our only powerful organization, which in firm hands may see us through the trouble." Set up a strong executive that "will not wabble." It will be exceedingly difficult to work within the constitution, but it is possible, and to show the "reform committee" is in deadly earnest, there is to be a meeting of West London practitioners next Tuesday, at which Dr. Fred. J. Smith will take the chair and resolutions be proposed which, if carried, will be followed by proceedings such as are possible within the terms of the "cast iron constitution." Thus, whether the Council resign or not, the inner circle will have no chance of evading a plain issue. Few now venture to deny that this

inner circle did prefer to sacrifice the profession rather than risk a defeat of the author of the bill.

It was the conviction of the assembly at the Queens Hall that they had been "sold" to save a socialistic government that made them refuse to hear Sir Victor Horsley. His somewhat domineering manners has previously rendered him unpopular, and it was well known he would defend the Council.

It has been rumored during the week that the Council were consulting lawyers as to the necessity of calling a general meeting. Innocent people thought a request from nearly 600 members would be imperative—law or no law. But I hear the articles are designed expressly to prevent any discussion of policy at a general meeting, and counsel's advice is that only a meeting of "the representative body" can do so. Formalities have been fulfilled to get such a meeting. Whether they resign or not the executive might not do amiss, if he doubt the feeling of their members, to summon both bodies and ask their opinions.

From the 1st inst. consumption has become notifiable in all cases, completing the policy inaugurated in 1908, when notification was made compulsory in Poor Law Institutions. In March, 1911, the system was extended to hospitals. The Local Government Board justifies the new order on the ground of the success that has attended the previous efforts to control the disease, the death rate from pulmonary tuberculosis having fallen from 18.25 per 10,000 in 1881 to 10.93 in 1909. The regulations lay down that nothing shall be done under them to subject a patient to any liability, restriction, prohibition, or disability affecting himself or employment or means of livelihood, and this policy is indicated in other ways. The register is to be a private document. Patients are to be told that if properly treated they may cease to be dangerous to others, and local authorities are authorized on the advice of their M. O. H. to circulate handbills, leaflets, etc., concerning the disease and the prevention of its spread.

The surgical treatment of osteoarthritis was illustrated at the Clinical Section (R. S. M.) by Messrs. Gordon Watson and Morriston Davies. The former showed a case affecting the hip on which he performed subtrochanteric osteotomy of the femur, which had alleviated the patient's pain. Mr. Davies showed a woman who has suffered for many years from dislocation of the patella and osteoarthritis of the knee joint. In May, 1910, the patella could only be partially replaced and she could not lift the leg from the bed. He opened the joint, removed a good deal of both surfaces of ge external condyle; then divided the extensor quadriceps on the outer side, freed the tendons of the gracilis and semitendinosus from their insertions into the tibia, and stitched their cut ends to the inner side of the patella. Longitudinal pleating of the capsule to tighten it on the inner side of the joint completed the operation, which was so successful that the patient celebrated the first anniversary of its performance by going to a dancing party and dancing hard.

Typhoid fever prevailed in Leicester during the past month, during which more cases were admitted to the isolation hospital than throughout the previous eleven months. The M. O. H. has prepared a special report on the epidemic, from which it appears that the consumption of raw mussels seems a likely cause, for his inquiries show that nearly all the patients had eaten some in the uncooked state. An outbreak at Sheffield is said to have been definitely traced to the same cause, all the cases having partaken of a parcel of mussels sent from the Southwest coast.

The Finsbury outbreak in September was investigated by Dr. Hamer, who found the most probable cause to be fried fish, which has been considered responsible for several other outbreaks in London. The report shows that ice cream was suspected at first in the neighborhood, but the investigation proved that less than half the sufferers (21 out of 56) had partaken of the suspected cream, but no less than 52 of the 56 had eaten of the suspected fish. Obviously, two or three cases might be considered as representative of the average number of sporadic cases and unconnected with the epidemic. Dr. Hamer finds support for the fried fish hypothesis in his study of the age incidence, topographical distribution, social condition, and other influences affecting individuals or family groups.

At Croydon and Wandsworth some cases occurred recently and watercress, being rather largely cultivated in the district, became suspected. The local authorities determined to investigate the probability of contamination of the long, narrow beds in which the plant is cultivated, as well as the water which is kept continually flowing along them and the mud of the bottom in which the cress grows. Planting out begins in February. The sprigs are generally obtained from a distance, as in this way an earlier crop is secured than from the soil. The river Wandle, from which the water is directed over the beds, receives sewage higher up and, though it has undergone purification, there has been a suggestion that some danger may be in that direction. The rain water from the roads drains into the river and may be a source of pollution. Another risk is from the pickers. Planks are thrown across the beds for their convenience and moved downward from time to time as necessary. A picker with ambulatory typhoid is a further possible danger.

In the list of honors usually conferred at the New Year half a dozen doctors are included. A knighthood is given to Dr. Benson, president of the Royal College of Physicians in Ireland; Dr. Collie, medical examiner to the London County Council and the Water Board; Dr. J. M. Davidson of the *x*-ray department, Charing Cross Hospital; Dr. G. H. Savage, consulting physician to Guy's Hospital and Earlswood Asylum; Dr. C. K. MacKellar, a Glasgow graduate in medicine, member of the New South Wales Legislative Council, and Dr. Windle, Pro-V.C. of the National University of Ireland. Dr. Newsholme of the Local Government Board, gets a C.B.

As if to show that the Government attaches little value to the order or to the profession, the same rank is given to the proprietor of Beecham's Pills! so successfully advertised as "worth a guinea a box" that the papers say his history from an humble position constitutes "a romance of trade."

Dr. Trevelyon's death is a great loss to Leeds, where he was Professor of Therapeutics in the University, Physician to the Infirmary, and held other offices. He was a distinguished graduate of the London University, M.D. with honors in several branches, and a degree in science also (1885-7). In 1901 he was elected F.R.C.P. and gave the Bradshaw lecture in 1903, taking for his subject tuber-

culosis and the nervous system. He edited for some time Braithwaite's Retrospect of Medicine, and contributed to *Brain* and other reviews and journals. A very learned man, he was called a "walking cyclopedia" among the students, who found him always able and willing to clear up their difficulties.

The death occurred on December 30 of Dr. J. F. Sutherland, F. R. S. Ed., Senior Deputy Commissioner in Lunacy for Scotland, at the age of 57. He was an Edinburgh graduate, M.B., C.M., 1878; M.D. with gold medal, 1880. He had been medical officer to Glasgow prison and later a consulting officer to the Barlinnie prison. He was secretary of the Commission on Habitual Offenders in 1894, and took part in the International Medical Congress at Moscow, Paris, and Madrid. He wrote a work on "Hospitals and Their Construction" and also on the "Insane in Private Dwellings," and an "ambulance *vade mecum*." He also contributed largely on insanity and criminology and similar subjects to societies, congresses, and journals.

Progress of Medical Science.

Boston Medical and Surgical Journal.

A Few Notes Upon Operative Measures for Tuberculous Knee Affections. H. W. Marshall.
Two Cases of Intracranial Cerebral Hemorrhage in the Newborn Relieved by Operation. C. C. Simmons.
Infant Feeding *au Naturel*. S. Delano.
A Case of Mild Anterior Poliomyelitis. W. N. Bullard.
Two Cases of Poliomyelitis Mistaken for Neuritis. T. A. Williams.

Surgery in Tuberculosis of the Knee Joint.—H. W. Marshall states that resections in adults are beneficial in a large percentage of cases, the final results depending upon the following factors: the patient's powers of resistance, skill in the performance of the operation, and the degree of postoperative care. Resections should be made as simple as possible. Diseased tuberculous bone should be cut away without attempting to remove it entirely, yet without leaving an overwhelming amount of necrotic material for physiological reparative processes to take care of when the disease is extensive. The vitality of the tissues should not be impaired by unnecessary mechanical injury, cauterization, or strong solutions, because tubercle bacilli cannot be eradicated by such applications, and because severe treatment produces necrosis that delays healing and retards union of the bones. The patella should be removed, the wound washed with normal salt solution, the capsule of the joint sutured, and a plaster cast applied. Special conditions often exist that demand special measures, as, for example, the use of bone plates. The question of drainage or tight closure can be decided only by the surgeon, for each individual patient, at the time of operation. Successful healing of wounds depends upon a proper degree of rest and freedom from mechanical movements and irritations; upon proper regulation of the blood and lymph supply; and upon favorable external physical and chemical stimuli.

Intracranial Hemorrhage in the Newborn.—C. C. Simmons reports two cases of this condition successfully operated upon. Both infants were born after instrumental labors; the first case presented symptoms of stupor, vomiting, and twitching of the limbs; the second case presented symptoms of dyspnea, cyanosis, and general convulsions. In both cases the operation performed was a short incision along the coronal suture, and through the latter and the dura underlying it, which incision was followed by the escape of a small amount of blood. The best treatment of any case of cerebral hemorrhage is an operation that removes all the clot, such as that described by Cushing, as there is the possibility of organization of any clot not removed, with the formation of adhesions and consequent irritative symptoms later in life. On the other hand, if the hemorrhage is large and extends below the tentorium, no operation yet devised will remove it all, and, if bilateral, a double or secondary operation must be done. Some infants bear the severe osteoplastic operation well, as is shown by the fact that Cushing did a double operation in one case with recovery, while in two other cases he performed secondary operations. It is, nevertheless, a much more serious operation than the evacuation of the blood through the suture. The operation done in these two cases was simple, rapid, and easy of execution and apparently warranted by the result.

Infant Feeding.—S. Delano makes a plea for a simpler and more natural method of feeding infants on cow's milk that has not been diluted to the extent that the stomach rejects it for want of a sufficient volume of curd to work upon. The stomach needs curds—a magma to get its grip upon—so that the organ may act like an efficient churn. Whole milk supplies this want. Some of the most general principles of infant feeding are not to lean too heavily on the tables of physiological chemistry, and to avoid the fallacy that because a baby's stomach rejects its food it is a weak stomach.

Mild Poliomyelitis.—W. N. Bullard reports the case of a girl eight years old, who had been thoroughly exposed to contagion from her brother, ill with anterior poliomyelitis. The patient developed an illness exactly one week later than her brother. Her illness, although the high temperature lasted but a short time, was a severe one, weakening the patient, who was a vigorous child,, and at the time of the attack and for some time previously had been in perfect health, so that she was in bed fourteen days and was still weak at the end of three weeks. There was in this attack no important gastrointestinal disturbance. The patient was for two days unwilling to eat and there was constipation. Once when pressed to eat she vomited, but this was evidently due to a temporary condition, and was a secondary symptom. The general hypersensitiveness of the nervous system was very marked. The absence of paralysis was a significant feature. The author is not certain whether or not the preliminary administration for three days of urotropin and the use for the same time of a gargle of peroxide of hydrogen had any influence in checking the severity of the ensuing illness.

Poliomyelitis Mistaken for Neuritis.—T. A. Williams reports two cases: one of paralysis of the legs, and the other paralysis of the serratus magnus, both of which were cases of poliomyelitis mistaken for neuritis.

New York Medical Journal.

The Effect of Tuberculin Treatment upon the Leucocyte Picture. M. Solis-Cohen and A. Strickler.
The Evolution of the Operating Table; Additional Data. W. S. Bainbridge.
A Case of Thoracic Tumor and Aneurysm of the Descending Thoracic Aorta, Treated with Salvarsan. G. R. Satterlee.
A New Muscle Resection Operation for Squint. R. G. Reese.
Rheumatism and an Unquestionable Remedy. L. Ott.
A Combination of Autopsy Tray and Warming Stage to Facilitate the Bleeding of Rabbits from the Postauricular Vein. G. A. Rueck.
The Present Status of Gonococcus Infection. R. M. Rawls.
The Ocular Manifestations Associated with Some Forms of Chronic Cyanosis. T. B. Holloway.
Periamygdalar Suppuration. N. Settel.
Deep Penetration of the Thigh by a Crochet Needle. F. Griffith.

Tuberculin and the Leucocytes in Tuberculosis.—M. Solis-Cohen and A. Strickler state that improvement in pulmonary tuberculosis is associated with an increase in the proportion of lymphocytes in the blood at the expense of the polymorphonuclear cells. As the patient gets worse the proportion of multinuclear cells increases at the expense of the lymphocytes. None of the other cells is affected by either process. As a rule, in consequence, the percentage of lymphocytes will be less and the percentage of multinuclears will be greater the more ad-

vanced the disease and the greater the amount of lung tissue involved. As a patient begins to improve there is usually an increase in the proportion of multinuclear cells containing one and two nuclei, the increase being often maintained for several weeks, but not indefinitely. Uninuclear, transitional, and eosinophile cells are unaffected by the stage, extent, or progress of the disease. The leucocytic picture in pulmonary tuberculosis corresponds with the patient's resistance to disease, rather than with the extent of the lesion. By means of the leucocytic picture it is often possible to estimate the resistive power and to obtain a fairly accurate estimate as to the chances for recovery. In all the author's cases there was an increase in the proportion of multinuclear cells with one and two nuclei during tuberculin treatment; in two cases, however, being preceded by a fall. In four of the six cases the lymphocytes were increased during tuberculin treatment, a slight intermediate fall, however, occurring in one after three months on the same dosage. Tuberculin given by the mouth in very small does, very gradually increased, apparently produces an alteration in the proportion of the different forms of leucocytes.

Evolution of the Operating Table.—W. S. Bainbridge presents additional data in support of his belief that the operating table he has devised contains original and improved features.

Thoracic Tumor and Aortic Aneurysm Treated with Salvarsan.—By G. R. Satterlee. (See MEDICAL RECORD, Vol. 80, page 993.)

Operation for Squint.—R. G. Reese describes a new muscle-resection operation for squint, the essential features of which are as follows: The line of incision is six millimeters from the circumcorneal vascular zone, thereby avoiding any marked reaction. The free dissection of the muscle from all tissues of the globe makes the operation a myectomy. The sutures are put in the scleral stump, avoiding traumatism by not sewing the sclera proper. The manner of placing the middle suture precludes the possibility of its pulling out. The "bridle" seen in advancements is avoided, motility is not limited, and a better cosmetic effect is given. The muscle is sutured to its original insertion and not to the corneal margin. The same result is eventually obtained in advancements, as the belly of the muscle becomes attached to the original insertion. The motility is increased in every case. The manner of placing the forceps insures the holding of all the fibers and the groove on its blade indicates the middle of the muscle.

Treatment of Rheumatism.—L. Ott reports favorable results in the treatment of rheumatism with acetylmethylenedisalicylic acid.

Autopsy Tray and Warming Stage.—G. A. Rueck describes a combination of these two forms of apparatus.

Gonococcus Infection.—R. M. Rawls discusses the various aspects of this subject.

Ocular Manifestations of Chronic Cyanosis.—T. B. Holloway cites from the literature, including his own cases, a total of twenty-seven cases of cyanosis retinæ that have been observed among the numerous reported cases of congenital heart disease. Ocular changes have also been observed in the absence of general cyanosis. In the majority of cases the discs were hyperemic and the disc margins blurred in varying degrees. In the two primary types of polycythemia, namely, polycythemia rubra megalosplenica and polycythemia hypertonica, in the secondary types of polycythemia, and in true polycythemia the fundus changes were of the mild type; that is, the discs were dusky red with hazy margins, and the veins were moderately distended and dark in color.

Peritonsillar Suppuration.—N. Settel discusses the symptomatology and treatment of this condition.

Penetration of Thigh by Crochet Needle.—F. Griffith reports the case of a woman whose thigh had been penetrated for a distance of three inches and a half by a large crochet needle which was removed intact without any resulting bleeding.

The Journal of the American Medical Association.

January 13, 1912.

The Nursing Infant.—H. Koplik states that the neglect of breast-feeding and the premature weaning of infants are prevalent evils. Mixed feeding does not seem to occur to the mind of the physician. The author notes the recent improvement in the higher education of the physician in regard to the diseases and hygiene of infants.

Cystitis Caused by Hexamethylenamine.—W. D. Fullerton reports a case in which a very pronounced cystitis was produced by the administration of hexamethylenamine and hexamethylenamine methylene citrate.

Cesarean Section.—By T. M. Burns. (See MEDICAL RECORD, vol. 80, page 106.)

Training Camp Method in Treatment of the Functional Neuroses.—T. J. Orbison has tried in thirty cases during the past ten years to apply the training methods used by athletes. The results have been uniformly good. The motto of every training camp is "obedience." Every necessary psychotherapeutic method is tried, according to the case, but it is rarely necessary to attempt any of the extraordinary methods of psychoanalysis.

Chloroform Fatalities.—P. W. Monroe reports six cases of fatalities within the past fifteen months from the use of chloroform as an anesthetic. Chloroform seems to be the anesthetic of choice in Mexico. In the first three cases the unfavorable symptoms supervened thirty-two to fifty-eight hours after the operation. In the last three death occurred early during the operation. Cessation of respiration was the first symptom noted in each case.

Abdominal Incisions in Pelvic Surgery.—C. G. Child describes what he considers an improvement on the Pfannenstiel incision in pelvic surgery.

Intravenous Injection of Salvarsan.—W. B. Dakin describes a new apparatus that he has devised for this purpose.

Fungous Tracheobronchitis.—G. H. Hoxie and F. C. Lamar report two cases of bronchitis in which careful examination of the sputum revealed the presence of fungous stalks as the only causative organism. Attempts to grow the fungi failed and their identity was not established.

Convulsive Movements of the Face.—A. Gordon states that there are three types of convulsive movements of the face: tic, facial spasm, and epileptic twitchings. As regards the last, they are usually associated with generalized epilepsy or with focal epilepsy of the same side. In some cases they may be confused with tic and facial spasm, but the most important differentiating feature is in the successive and progressive contraction of the different facial muscles instead of a simultaneous contraction of an entire half of the face seen in facial spasm of non-cortical nature. Facial tic is characterized by a sudden abrupt contraction of one or several muscles, always the same, but not corresponding to a well-defined nerve region. It has a tendency to spread and invade other functions, and can be controlled to a certain extent by the patient's will. It is largely a habit neurosis, and its chief characteristic feature lies in exaggeration or disfigurement of physiological gestures or mimicry. In true facial spasm, on the other hand, there is no tendency to reproduce physiological acts and the convulsive movements are limited to the well-defined areas of nerves. While in the majority of cases the spasmodic contraction of the face is caused by peripheral irritation, organic lesions higher up may be possible factors, as some of the clinical observations indicate.

Postoperative Psychoses.—H. P. Cole emphasizes the importance of the preventive psychic treatment by judicious management before operation and during its performance and during convalescence. Care taken to relieve discomfort and pain, and the use of alcohol rubs or, at most, a mild sedative, will usually eliminate insomnia, which is an important factor. The non-use of morphine, the early and frequent use of the rectal tube to remove tympanites, and the substitution of a soft diet soon after operation, with a rapid return to the normal preoperative diet, are not only measures of excellent physiological therapeutics, but also tend to distract the patient's mind.

Phenol Gangrene.—F. Buckmaster reports a case of an extensive gangrenous ulcer of the leg caused by the application of a phenolated ointment.

Hemiatrophy of the Tongue.—E. W. Scripture reports a case of this condition associated with defective speech in a girl fifteen years of age.

Tetanus Prophylaxis.—O. Berghausen and C. E. Howard state that the treatment of punctured, lacerated, and penetrating wounds, especially these from giant crackers and blank cartridges, should include thorough cleansing and removal of foreign matter, application to the wound of a 5 per cent. phenol-hydrochloric acid solution, enlarging the opening if necessary and using a general anesthetic if called for, then packing the wound lightly with gauze soaked in the phenol-hydrochloric acid solution, dressing the wound, and changing the dressing daily. Immediately after the first dressing 1,500 units of antitetanic serum should be given subcutaneously.

Adiposis Pituitary Syndrome.—T. A. Williams and J. Dunlop report a case in which they diagnosed a neoplasm in or around the pituitary body, on the basis of the deep headaches, the heaviness and sleepiness, the hypertrophy of the fatty tissues, and the changes in the visual field.

Foreign Blood in the Treatment of Hemophilic Bleeding.—J. H. Sayer states that in a case of obstinate hemorrhage from a wound in a hemophilic patient the bleeding was stopped at once by a few drops of the author's own blood applied to the cleansed bleeding surface.

Recurring Adenoids in Children.—L. Fischer suggests the importance of looking for syphilis as a possible cause in recurring cases of adenoids.

Medical Examining Boards.—B. K. Hays describes the practical methods which are in use by the North Carolina board to supplement the written examination, including the use of the obstetric manikin, physical examinations, identification of surgical instruments, the use of drugs and of the microscope, and a few practical chemical tests. Reciprocity has been one of the most serious problems, and to meet it the board grants it on the merit of the individual, according conditional reciprocity to a few States but reserving the right to reject any applicant it thought best. The board will not register any physician through reciprocity until he has appeared before the board in person.

Visceral Lesions of Poliomyelitis.—S. Flexner, F. W. Peabody, and G. Draper state that in poliomyelitis the main injury appears to be inflicted on the nervous organs, next on the lymphatic organs, and last on the parenchymatous organs. Of the last, the focal necrotic lesions of the liver are especially prominent. Whether the organic lesions, exclusive of those of the nervous system, are to be attributed to parasitic action or to the action of toxic elements of parasitic origin is a matter of conjecture. But the polymorphonucleosis of epidemic poliomyelitis is caused not only by the lesions of the nervous system, but also by lesions of the lymphatic tissues and liver. This consideration will serve to explain certain discrepancies in the cell-findings in the cerebrospinal fluid and in the circulating blood.

Paroxysmal Tachycardia.—H. M. Rich reports a case of this condition.

Unnecessary Adenectomies.—C. B. Younger believes that there are cases in which the operation of adenectomy has been unnecessarily performed and that there is sometimes a tendency to careless diagnosis of these cases. There are other obstructions of breathing that will cause the adenoid facies, such as hypertrophic rhinitis, which is quite as prevalent in childhood as at any other time of life. A high arched palate and protruding front teeth, a very large hypertrophy of the faucial tonsils, or a slight anterior deviation of the spine protruding on the nasopharyngeal space have also been known to cause the symptom-complex of adenoids. Little or no disturbance of nasal breathing may occur from fair-sized adenoid growths in a spacious nasopharynx, and operation may hardly be required.

Aneurysm of Innominate.—J. F. Baldwin reports a of this condition which was successfully operated upon by synchronous ligation of the subclavian and carotid. The aneurysm extended about 1½ inches above the clavicle.

Intestinal Hemorrhage in Tuberculosis.—Le R. S. Peters and E. S. Bullock report five cases of marked hemorrhage from the bowel occurring in tuberculous patients. One of the hemorrhages resulted fatally.

Double Tubal Pregnancy.—E. T. Milligan reports a case of this condition successfully operated upon.

The Lancet.

January 6, 1912.

Sensory Disturbances from Cerebral Lesions.—H. Head and G. Holmes present a general conception of the mechanism underlying sensation, based upon a study of human beings in whom disease, accident, or surgical interference has produced some stationary lesion. They

conclude that the brain-stem between the nuclei of the posterior columns and the final termination of all sensory paths in the optic thalamus is the seat of the following changes. The impulses for pain, heat, and cold continue to run up in separate secondary paths on the opposite side of the nervous system to that by which they entered. They receive accessions from the regrouped afferent nerves of the head and upper part of the neck. Although these paths are frequently affected together they are independent of one another, and any one of the three qualities of sensation may be dissociated by disease. Lesions of the spinal cord tend to diminish simultaneously all forms of painful sensibility, but with disease of the brain-stem the gross forms of pain and discomfort may pass to consciousness, although the skin is analgesic. This applies not only to painful pressure but to the discomfort produced by excessive heat. The impulses concerned with postural recognition part company with those for spacial discrimination at the posterior column nuclei. Up to this point they have traveled together in the same column of the spinal cord, but as soon as they reach their first synaptic junction they separate. Above the point where they enter secondary paths the power of recognizing position and passive movement can be affected independently of the discrimination of two points and the appreciation of size, shape, and form. It would seem as if those elements which underlie the power of localizing the spot touched or pricked become separated from their associated tactile impulses before they have actually come to an end in the optic thalamus. The long connection of localization with the integrity of tactile sensibility is here broken for the first time. All these changes are preparatory to the great regrouping which takes place in the optic thalamus.

Surgical Treatment of Tuberculous Arthritis in Children.—H. H. Tubby states that the object of every form of treatment of tuberculous arthritis must be: (1) to eradicate the disease; (2) to preserve the functions of the part; and the question is whether these results are more frequently obtained by climatic and conservative measures or by so-called radical operations. It appears that the balance of experience gained in treatment during the last decade shows that conservative treatment is the better in childhood. Time is saved, the resultant deformity is diminished, and there is less risk of generalized tuberculosis when the treatment is non-operative.

Erythremia.—W. Hale White reports three cases of this disease, known also as Osler's disease, Vaquez's disease, and splenomegalic polycythemia. Each case shows features of interest. The cases do not in any way indicate why the blood should hypertrophy to the extraordinary extent that it does in this condition. In none of them could any cause for the polycythemia be discovered, and it was clear from the history of the first patient that the disease had begun only three years before the author saw him, and then the patient's attention had been called to it by his becoming dusky; in the other two the diagnosis was only reached by a routine examination of the blood of patients whose spleens were enlarged, for neither of them was cyanotic, and thus they illustrate that the disease should not be called "splenomegalic polycythemia with cyanosis," as is sometimes done.

Diagnosis and Treatment of Chronic Duodenal Ulcer.—B. G. A. Moynihan states that the diagnosis of duodenal ulcer depends first and foremost (indeed almost exclusively) upon the anamnesis. The history enables a diagnosis to be made with a risk of error which, when tested by the operation, is found to be extremely small. The second point in the diagnosis is the discovery during the stage of active ulceration, during the "attacks," of an increased secretion of free HCl. Thirdly, there is a striking and possibly characteristic picture given upon *x*-ray examination after a bismuth meal. The stomach, in the presence of active ulceration in the duodenum, seems to have an enhanced activity in respect to both its secretory and its motor functions. Fourthly, the diagnosis depends upon the discovery of occult blood in the feces during the stage of active ulceration, if daily examinations of the feces are made. In the later stages, of course, the appearances due to slight or severe stenosis may be presented. The physical signs elicited upon an examination of the abdomen are only of the slightest value until such obstruction has developed. The only operation appropriate for the great majority of the cases is gastroenterostomy. In nine out of ten cases operated upon the author has examined and removed the appendix. In eight out of ten cases in which the appendix was removed this organ gave evidences of long-standing and advanced disease.

Foreign Bodies.—R. Parker reports a series of twelve cases in which foreign bodies of various kinds were removed from different parts of the body.

Fungi in Tropical Bronchomycosis.—A. Castellani notes that the fungi so far observed in Ceylon in cases of bronchomycosis are 12 different species of endomyces, the commonest being *Endomyces tropicalis, Saccharomyces krusei,* various strains of actinomyces and streptothrix, fungi of the genera aspergillus and penicillium, and several other fungi which so far the author has not determined.

Treatment of Glaucoma.—J. H. Parsons states that the formation of a filtering cicatrix holds out the best hope of alleviating chronic glaucoma.

Lymphatic Varicocele.—F. C. Madden reports three cases presenting the usual clinical signs and symptoms of varicocele, but in which the swelling was due to the presence of tortuous coils of very thin-walled, dilated lymphatics in the substance of the spermatic cord. This condition, the author believes, is a manifestation of filariasis, though he has not succeeded in finding filarial embryos in the blood.

Prevention of Tuberculosis.—J. Sim Wallace alludes to the importance of increasing the resistance of the individual and of preventing the entrance of the tubercle bacilli through carious teeth, and diseased tonsils and adenoids.

Counting Leucocytes.—R. A. P. Hill describes a new method by means of which a total and differential count of leucocytes may be done simultaneously.

Cerebral Malaria.—W. T. Quaife reports the case of a boy aged 18 years in whom malaria manifested itself by deep unconsciousness lasting for 48 hours. Recovery followed the use of bihydrochloride of quinine administered in 30-grain doses per rectum.

Pulque and Pulque Drinking in Mexico.—J. Bland Sutton describes the national drink of Mexico, pulque, which is an alcoholic beverage obtained from the fermentation of the sap of the maquey (*Agave mexicana*).

British Medical Journal.

Jejunal and Gastrojejunal Ulcers. A. W. Mayo-Robson.
Urethral Calculi, with Special Reference to Encysted Calculi of the Prostatic Urethra. K. W. Monsarrat.
A Case of Calculi of the Prostatic Urethra. R. L. Spittel.
An Unusual Urinary Deposit of Calcium Carbonate. W. H. Brown.
A New Cell Proliferant; Its Clinical Application in the Treatment of Ulcers. C. J. Macalister.
The New Cell Proliferant; A Note on the *Symphytum Officinale* or Common Comfrey. W. Bramwell.
Treatment of Puerperal Septicemia by Vaccines. A. Hawkyard.
Salvarsan in Yaws. H. Alston.
An Examination of Abor Arrow Poison. F. N. Windsor.

Jejunal and Gastrojejunal Ulcers.—A. W. Mayo-Robson states that jejunal and gastrojejunal ulcers, which are more common than the profession is quite willing to acknowledge, probably never occur except as a complication of the operation of gastroenterostomy. The author believes that these ulcers are due to the fact that sufficient care is not exercised in dieting patients who

have undergone the operation of gastroenterostomy, and that hyperchlorhydria and sepsis combine to produce ulceration. The dangers of jejunal ulcer arise not only from painful indigestion (the pain simulating that of duodenal ulcer, only varying in position), but also from a recurrence of symptoms of ulcer often associated with hemorrhage, and not infrequently ending in perforation. If after a period of good health subsequent to the operation of gastroenterostomy a patient begins to complain of acidity, flatulence, and discomfort after meals; followed after a time by definite pain from an hour to two or three hours after food, and relieved temporarily by taking milk or some other light diet, or some form of alkali such as sodium carbonate; if the pain occurs on the left of the umbilicus, and is associated with marked tenderness and rigidity of the left rectus, the suspicion of ulcer of the jejunum will arise. The complication of hematemesis or melena, or even the presence of occult blood in the feces, will make the diagnosis fairly certain; but if, with all these symptoms, a swollen and tender loop of bowel can be felt in the region of the anastomosis, or below and to the left of the umbilicus, the surgeon can no longer be in doubt as to the nature of the disease. In extreme cases of this condition the author has found the operation of jejunostomy most safe and useful.

Urethral Calculi.—K. W. Monsarrat states that urethral calculi are either calculi which have been formed in the urinary passages above and have lodged in the urethra or calculi which are formed in the urethra itself, or in some cavity or channel communicating with it. The lodged or impacted calculi of the urethra are vesical or renal in origin. Encysted urethral calculi lie in pockets or diverticula communicating with the urethra.

Calculi of the Prostatic Urethra.—R. L. Spittel notes that the true prostatic calculi are formed in the substance of the prostate gland and are entirely distinct in origin and nature from urinary calculi.

Urinary Deposit of Calcium Carbonate.—W. H. Brown reports the case of a man aged sixty-five years who was presumably suffering from granular kidney, and whose illness began with headache, followed later by nausea and vomiting. He got progressively worse, gradually passed into a comatose state, and died three weeks after the onset of symptoms. The urine, which at no time contained more than a very small quantity of albumin, showed during the second week of illness a very large number of crystals of calcium carbonate.

Comfrey, a New Cell Proliferant.—C. J. Macalister states that from time immemorial the *Symphytum officinale* or common comfrey has been recommended as a dressing for sores and ulcers of various kinds. The root contains a crystalline solid which possesses the same empirical formula as allantoin. Solutions of this substance have been found by the author to possess the distinct property of stimulating the growth of epithelium on ulcerated surfaces. It may even be administered internally in the treatment of gastric and duodenal ulcers.

Comfrey, the Cell Proliferant.—W. Bramwell alludes to the efficacy of this substance in the treatment of ulcers. It is also of value when administered internally in gastralgia, and as an external application in pruritus ani.

Vaccines in Puerperal Septicemia.—A. Hawkyard reports four cases of puerperal septicemia, chiefly of streptococcus origin. The cases all recovered under the administration of autogenous vaccines.

Salvarsan in Yaws.—H. Alston concludes from his experience in the treatment of 500 cases that salvarsan is a specific for yaws and that there is no danger attending its use in this disease.

Abor Arrow Poison.—F. N. Windsor states that the arrow poison used by the Abors is a paste made by pounding the soft parts of *Croton tiglium* plant.

Berliner klinische Wochenschrift.

January 1, 1912.

Endogenous Depression.—Bonhoeffer applies this term to a condition which requires differentiation from neurasthenia. The latter he holds to be of rare occurrence, while the former is not only common, but divisible into several kinds. How are endogenous affections isolated? The hereditary element is the first to bear in mind, as manifested very early in life as a certain temperament. Especially important in this connection is the hypochondriac tendency, and next in order the periodicity, as expressed in many ways—insomnia, palpitation, nightmare, imperative concepts. More somatic in character are periodic dyspepsia, diarrhea, urticaria, asthma, etc. Certain affections which recur at long intervals become serial or cumulative, notably migraine and scintillating scotoma. From another side this pseudoneurasthenia is expressed by periodic depression such as underlies the supervention of manic-depressive insanity. In contradistinction from neurasthenia the symptoms of endogenous depression set in suddenly and sharply and disappear as sensationally. Since they are referred to particular organs, the patient may seek aid for gastric, cardiac, or other somatic disturbance. Three illustrative cases are cited. The first occurred in a cook who had suffered much for months from nausea, palpitation, anxiety, insomnia, bad dreams, vertigo, weakness, etc. Her symptoms were aggravated in the morning. Objective examination revealed nothing worth mentioning. There had been a similar experience four years before. There was a very palpable hereditary element, for both parents had been melancholic suicides. The patient rapidly improved, all the symptoms tending to disappear at the same time. The prognosis, however, is unfavorable. The second case was characterized to a much less extent by heredity and periodicity. Naturally cheerful and active, the temper changed to one of depression and diminished executive ability, so that the occupation of locomotive engineer had to be given up. Nothing was found objectively and the patient had been suspected by his superiors of shamming illness for some purpose. The third patient suffered from typical cyclothymia.

Sympathoma Embryonale.—Under this term Pick describes a typical malignant tumor of the sympathetic nervous system. It is characterized histologically by tissue exactly resembling the embryonal structure of the sympathetic ganglia. Such growths necessarily occur in the midst of other tissues and not in the continuity of nerves, the nearest approach to a pure localization being seen in case of tumor of the sacrococcygeal gland. In addition to the primary localization, metastases occur. By all odds the most common incidence is in the suprarenal glands. Some eighteen cases are to be isolated from the literature, including one herewith reported. The first one goes back to 1885, reported by Dalton as a lymphoma. In 1891 Marchand published the second case and recognized its possible character, but the tumor, seated in the right suprarenal body, showed no clinical malignancy. Succeeding cases were usually termed sarcoma or glioma, the latter when occurring in the nerve centers. French authors introduced the term "parasympathoma" in 1907. The very thorough monographic study will be continued in another number.

Salvarsan in Pernicious Anemia.—At a recent meeting of the Toronto Academy of Medicine, Dr. W. B. Thistle reported two cases of pernicious anemia which he had treated by injections of salvarsan. One of the patients had had a number of severe relapses. Four injections of salvarsan were given in the muscles. In the second case there were given also four injections. Both patients improved very decidedly.—*Canada Lancet.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

PERSONAL HISTORY.

HABITS.—The question of the habits of an applicant from a life insurance point of view is confined to the use of alcohol or drugs. The subject is one of the most important in the selection of risks, and there is none that involves so much trouble and uncertainty on account of the strong inclination to suppress and distort the truth, even among applicants whose statements in other respects may be relied upon. This may be illustrated in part by the experience of the writer who had a small degree of confidence at one time in a written statement signed by the applicant whose habits were questioned, in addition to the regular report, to the effect that his mode of life was all that could be desired. This faith was soon dissipated, however, when subsequent and reliable investigation revealed excessive indulgence by a good proportion of the individuals who had signed these declarations.

An examiner, then, should not rely too much on the assertions of those who are suspected of using drugs or consuming an immoderate amount of alcohol. It is, unfortunately, necessary to ask him at times to make further inquiry, even though he has made a favorable report, when the company has reason to believe from other sources that the habits of the applicant are not what they ought to be. The examiner should give all the facts acquired in his investigation and may rest assured that information furnished by him will be treated as strictly confidential. The company does not expect the examiner to act the part of a detective and he will, as a rule, be requested to investigate further only when he is personally acquainted with the applicant. Occasionally, however, even though the applicant is unknown to him, the examiner may be asked to make some inquiry if the community in which they reside is a small one where everyone is more or less familiar with the affairs of others. Service of this kind is included among the duties of the medical examiner, as he is depended upon to render all the assistance in his power toward guarding the interests of the company and excluding poor risks. An examiner may have known an applicant for a considerable length of time and not be cognizant of any bad habits on the part of the latter. In this event, inquiries conducted in a quiet, tactful way among mutual friends and business acquaintances will usually elicit the desired information.

Alcohol.—It is not commonly contended that the individual who uses alcoholic beverages in a *strictly* moderate way is to any appreciable extent a less desirable risk than the total abstainer. The tolerance of alcohol varies with the individual. One man may drink a glass or two of wine or spirits a day with impunity, while another can not indulge even to this extent without physical deterioration. It may be stated in a general way, however, that the total abstainer is less likely to become an intemperate user at a later date than the one who habitually drinks alcohol in moderation, for the former is less exposed to the temptations of the bar-room, club, or the private closet in his home. The question arises, what constitutes strictly moderate drinking? Some men who pride themselves on their moderation would feel hurt at the suggestion that they drink more than is good for them, and yet are in the habit of taking five or six, or even more, drinks a day. These men are apt to resent close questioning when the examiner tries to get some definite idea of the amount of alcohol consumed by them. Then, again, there are the individuals who go on several (three or four) short sprees a year and drink little or nothing in the intervening period. It may be accepted that, as a rule, those who continuously indulge to the extent of about five or six drinks a day without feeling any the worse for it are more likely, eventually, to suffer from ill effects of some kind than those who get drunk occasionally and leave alcohol alone in the interval.

Immoderate drinkers of all classes should be rejected, but, notwithstanding the great care taken by insurance companies to keep such applicants off the books, a number of them will succeed in securing policies owing to the difficulties already alluded to. The number of these undesirable risks can only be kept down by maintaining a high standard among the examiners and agents, and in securing reports from other reliable sources. Part of the difficulty may be laid to the failure of medical examiners to agree on the question as to what constitutes strictly moderate drinking. Medical men who take five or six drinks a day themselves are inclined to adopt a complacent attitude towards the habits of those who indulge to the same extent or even a little more, while the abstaining examiner may be too severe on those who are really moderate drinkers. The examiner should state, as far as possible, the actual daily quantity imbibed by the applicant, instead of using such ambiguous terms as "temperate" or "moderate."

The kind of beverage used seems to make little difference. Beer is popularly supposed to be less injurious, but this idea is poorly founded, and its fallacy is ably maintained in the following quotation from an article by the eminent actuary, Emory McClintock, the ultimate results of alcohol also being referred to in the remarks: "Yet the difference between those who drink beer and those who drink water is unmistakable, while the loss on beer drinkers has been almost the same as upon wine and spirit drinkers. Among wine and spirit drinkers a large part of the extra loss is upon actual drunkards, while the remainder must be ascribed to the injurious effects upon the constitution of supposedly moderate though really immoderate indulgence. Among beer drinkers pretty much the whole of the extra loss, it would seem, must be attributed to constitutional effects. It is the danger of falling into the habit of intoxication that makes spirit drinking the more formidable of the two; while undoubtedly the habit of drinking either beer or wine or spirits beyond a certain medical limit, not well defined because it cannot be the same for all constitutions and usually exceeded by those who drink at all, tends in many cases towards disease. Finally, it may be questioned very seriously whether the physicians should not fix their limit of safety for any individual at a lower point for beer, measuring by alcoholic contents, than for spirits; that is to say, whether there is not an injurious element in beer apart from the alcohol which it contains.

"There is no reason to distrust the general results of this investigation. It coincides with all previous reasonable belief and expectation. It does not show that those who drink only occasionally and not to intoxication, or those who drink habitually but lightly, are in any way injured. It does not show that all of those who drink heavily must, therefore,

necessarily die prematurely. It does show, however, that there is enough injury done to a sufficient number of individuals to make the death loss distinctly higher on the average. Again, it is admitted that death losses in excess among drinkers are not necessarily due always to drink. The coincidence between excessive drinking and lower vitality may be partly due to bad risks taking to drink, as well as to good risks becoming bad because of drink. On the whole, however, the teetotal habit, not only before but after middle age, must be counted as a favorable indication in judging of proposals for insurance from persons not known to be careful and moderate in the use of beverages."

The well-considered conclusions of Mr. McClintock are emphasized by the experience of certain companies which divide their policy holders into abstaining and non-abstaining classes on the ground that it is unfair for the former class to be penalized by paying the larger premium required to meet the greater mortality in the latter class. Dr. T. F. McMahon recently read an article (MEDICAL RECORD, Vol. 80, No. 23) on the comparative mortality in these classes in the company which he represents. The statistics presented by him are practically the same as those gained from the experience of the other companies working on similar lines, and are the more impressing because they deal with comparison between total abstainers and strictly moderate drinkers and exclude immoderate drinkers as far as possible. In a resumé of these statistics it is seen that during the 45 years from 1866 to 1910 the number of actual death claims in the total-abstainer class was 8,988, as against 12,754 expected; in the non-abstaining class the actual number of deaths was 14,711, as against 15,794 expected. In other words, the percentage of actual to expected deaths in the abstainers' class was 70.47, while in the non-abstaining section it was 93.14. The mortality saving in non-abstaining class was, therefore, 3,766 lives during the 45 years, while that in the non-abstaining class, with a larger business, was only 1,083 lives. If the loss ratio had been as high in the abstaining section as it was in the non-abstaining section the mortality saving would have been only 875 lives instead of 3,766. If the loss ratio in the non-abstaining section had been as low as in the abstainers' section, the mortality saving would have been 4,664 lives instead of only 1,083. This makes the mortality saving an average of 4.3 times as great in the abstaining class as in that of the non-abstaining. The examiner can readily understand how poor a figure a class of those would cut who habitually drink five to seven times a day, if compared with even the non-abstainers' class referred to in the above figures in which every effort is made to exclude those who are not strictly moderate in the use of alcohol.

If the applicant has resorted to some form of cure for alcoholism, this should be clearly reported, as well as any lapses or subsequent treatments. It is important to know, furthermore, whether the applicant has been a total abstainer at all times since the cure, as otherwise the risk should be rejected. Some Keeley graduates are insurable on an endowment plan if time enough has elapsed to indicate that there will be no lapse and the applicant has fully abstained from drink in the meantime.

In his efforts to procure information the examiner will have to use all his tact and diplomacy, for these applicants will often resent any inquiry or will prevaricate in regard to their drinking. The questioning should, therefore, be carried out in a good-natured way, as a brusque manner and a too-pointed cross-examination will often lead to the defeat of the examiner's efforts to obtain the facts. The same suggestion applies when the applicant's friends are approached, for if they become suspicious of the questioner's motives they are very apt to make light of the matter or refuse point blank to give any information. Before the authorities at the home office can act on these cases they must have in their possession a full knowledge of the number of drinks consumed daily by the applicant, the maximum amount taken in any one day, the number of times, if any, he has been intoxicated, and the date of last intoxication.

Drugs.—Detection of the drug habit is more difficult than in the case of the immoderate use of alcohol. A drug habitué will usually lie without the least compunction or hesitation in regard to his weakness, and the examiner must, therefore, depend largely in his conclusions upon the general appearance and behavior of the applicant and upon current gossip. These unfortunates are especially bad risks on account of the wretched condition which awaits them and because the possibility of any escape from or effectual resistance to the intense longing becomes more and more remote as the quantity of the drug is inevitably increased while the mental and physical forces weaken. For some time after the habit has fastened itself upon the victim, there is little or no outward sign. Sooner or later, however, symptoms begin to appear in the form of colorless, sometimes clammy, skin, averted looks, contracted pupils, nervous irritability, or mental and physical lassitude. The presence of one or more of these signs should arouse the suspicion of the examiner and inspire him to look further into the habits of applicant; also to inspect the shoulders and arms for the presence of scars from the use of the hypodermic syringe.

Why Physicians Who Are Good Business Men Are in Demand by Insurance Companies as Examiners.—Charles T. Cutting believes that he is expressing the sentiment of the greater number of physicians and surgeons throughout the country when he states that now, as never before, the members of the medical profession find that to be successful the practice of medicine must rest upon business principles, and that no man can give proper thought and time to the study of disease and its care if harrassed by financial difficulties. Dr. Cutting argues that especially do the insurance companies look out for a business man as an examiner. The business physician is appreciated more to-day by the accident and liability companies than by the life companies, for the reason that experience has shown the value of medical examinations in cases of claim, as well as for the underwriting department, and it has been demonstrated that some physicians make most valuable claim adjusters, when this business instinct has been developed, and once employed in this capacity and making good, a permanent position with the insurance company is certain. The writer proves to his own satisfaction that the career of an insurance examiner is more profitable than that of the average general practitioner and is likely to become even more so than at present. Dr. Cutting gives a list of ten necessary qualifications for success as an examiner for accident, health, and liability insurance companies and concludes with expressing the opinion that the better qualified candidate for such a position is the physician who has a practical knowledge of business rather than one who can see nothing but science and performs his work in a routine, though highly professional manner.—*Lancet-Clinic*, December 9, 1911.

Book Reviews.

Diseases of the Ear, Nose, and Throat, Medical and Surgical. By Wendell E. Phillips, M.D., New York City. Illustrated with 545 half-tone and other text engravings, including 31 full-page plates, some in colors. Philadelphia: F. A. Davis Co., 1911.

The only criticism we have to make on this book is that it is too ponderous for comfort. As is implied in the title it covers three special fields. The author's purpose has been "to write a practical, accurate, and concise treatise bearing the approval of personal experience." Part I, covering 28 chapters, 405 pages, is devoted to the ear; Part II, 4 chapters, 85 pages, to the influence of general diseases upon the ear, nose, and throat; Part III, to the nose and accessory sinuses, the pharynx and fauces, and the larynx respectively. There is an excellent chapter on tracheoscopy and bronchoscopy. The formulary of the Manhattan Eye and Ear Hospital is appended and an excellent index closes the volume. Dr. Phillips is to be congratulated on the results of his labors. He has not simply added one more to the long list of treatises, but has introduced many original illustrations. The chapters on the labyrinthine diseases are full and up to date. That on malignant neoplasms of the larynx is rather meager. In fact the portion devoted to the ear has not only the larger part of the space but seems to have had the major part of the author's attention.

Textbook of Embryology. By Frederick Randolph Bailey, A.M., M.D., formerly Adjunct Professor of Histology and Embryology, College of Physicians and Surgeons (Medical Department of Columbia University), and Adam Marion Miller, Instructor in Anatomy, College of Physicians and Surgeons (Medical Department of Columbia University). Second Edition. With five hundred and fifteen illustrations. Price $4.50. New York: William Wood and Company, 1911.

The popularity of this textbook is attested by the fact that a second edition has been called for within two years of its first appearance. The book consists of two parts, the first one being devoted to the questions of general development—the cell, the sexual elements in the formation of the organism, the maturation of ovum and spermatozoa, fertilization, segmentation, germ layers, and fetal membranes are the separate subdivisions treated. Organogenesis is considered in the second part of the book, the development of the various tissues, viscera, and organs of special sense being fully described. Each chapter is followed by practical suggestions for procuring and preparing material for class study. An appendix reviews general histological technique.

The book is decidedly a good textbook, clearly written and very amply illustrated. It should prove of much use in reading collateral with practical courses in embryology and forms a good introduction to the study of histology and gross anatomy.

Currents of High Potential, of High and Other Frequencies. By William Benham Snow, M.D., author of "A Manual of Electro-Static Modes of Application, Therapeutics, Radiography, and Radiotherapy," "Therapeutics of Radiant Light and Heat and Convective Heat"; editor of the Journal of Advanced Therapeutics, and late Instructor in Electro-Therapeutics in the New York Post-Graduate School, etc. Second edition. Price, $3.00 net. New York: Scientific Authors' Publishing Company, 1911.

In no other department of therapeutics is there greater diversity of opinion, methods, and apparatus than in that devoted to the medical application of electricity. Dr. Snow has brought out a second edition of a work in which, in addition to the consideration of the high frequency currents of great potential, he gives special attention to great potential in association with the lower rates of frequency. The high potential currents of lesser frequency, says the writer, "exert the most favorable effects upon acute and chronic inflammatory conditions, especially those in which no germs are present." The first edition of the book has been considerably enlarged and partly rewritten. The developments in methods and their application in the treatment of hypertension by the d'Arsonval current, as well as the employment of direct d'Arsonvalization in the treatment of infection, have received consideration in the new edition. The findings and standards adopted by the committee of the Electro-Therapeutic Association devoted to the standardization of physical therapeutic measures have, the writer states, been closely adhered to in the present edition. A scientific basis for the employment of electricity and other modalities cannot as yet be said to be established. It is a consummation devoutly to be wished. Meanwhile the enthusiastic and authoritative way in which the subject is presented by this author is more or less acceptable.

Case Histories in Neurology. A selection of histories setting forth the diagnosis, treatment, and post-mortem findings in nervous disease. By E. W. Taylor, A.M., M.D., Instructor in Neurology, Harvard Medical School; Assistant Physician, Department of Neurology, Massachusetts General Hospital; Visiting Neurologist, Long Island Hospital, Boston. Boston: W. M. Leonard, 1911.

This is the latest of the "Case History Series," issued by the same publisher. It serves a purpose in setting forth certain fundamental facts regarding the symptomatology, diagnosis, treatment, and pathological findings in the more frequent disorders of the nervous system. One hundred and fourteen actual cases are reported in illustration of definite disease processes. The subject matter is arranged, after the anatomical method of division, into peripheral, spinal cord, and brain diseases. These are followed by disorders for which a definite anatomical basis has not yet been found; and lastly by affections characterized by disorders of function, the neuroses. These main divisions are each preceded or followed by explanatory sections on principles of diagnosis and treatment. There are thirty-seven figure drawings in the book, all original and of practical value. The work should prove to be of greater value perhaps to the student and general practitioner than to the neurologist. The less frequent and obscurer conditions occasionally met with by the latter are eliminated. We are unable to find described or illustrated clinically some symptoms of diagnostic value in localizing certain cerebral lesions, for example, the Wernike hemiopic pupillary reflex, the Weber syndrome, etc. The case histories are presented on the principle developed for medicine by Prof. W. B. Cannon. The style is clear and concise, and the book is a welcome addition to clinical neurology.

An International System of Ophthalmic Practice. By Walter Pyle, A.M., M.D., Philadelphia, Member of the American Ophthalmic Society. Pathology and Bacteriology by E. Treacher Collins, F.R.C.S., Surgeon to the Royal London Ophthalmic Hospital and Ophthalmic Surgeon to the Charing Cross Hospital, etc., and M. Stephen Mayou, F.R.C.S., Surgeon and Pathologist to the Central London Ophthalmic Hospital, etc. With three colored plates and thirty-seven figures in the text. $4.00 net. Philadelphia: P. Blakiston's Son & Company, 1911.

This volume of 558 pages is well printed and fully illustrated. The names of the authors are a sufficient guarantee of the excellence of the work. Chapter I deals with Aberrations in Development. Those connected with the primary and secondary eye vesicles, the invaginating surface epiblast, the mesoblast, and the orbitonasal fissure are considered in detail. Neoplasms are discussed in Chapter II. In the chapter entitled "Derangements of the Circulatory Fluids of the Eye and of the Vessels in Which They Are Contained," glaucoma, as well as albuminuric retinitis, and arterial sclerosis, are quite fully considered. The subject of injuries occupies Chapter IV. Under the heading "Inflammation" are considered: (*a*) The changes common to all inflammatory processes, (*b*) the modifications they undergo in the various structures of the eye, (*c*) the method of infection of the ocular tissues. This chapter is embellished by some admirable colored plates. A chapter on "Parasitic Diseases Affecting the Eye," "Degeneration," and an appendix giving practical methods of obtaining, examining, and preserving specimens follow. The work is written in a masterful manner by men who are recognized authorities on the subjects treated. It forms a valuable number in the volumes that go to make up the system of which it forms a part. The reviewer most sincerely commends it to all ophthalmologists.

Die Differentialdiagnose zwischen Magengeschwür und Magenkrebs. Die pathologische Anatomie dieser Erkrankungen in Beziehung zu ihrer Darstellung im Röntgenbilde. Von Prof. Dr. V. Schmieden. Mit 42 Abbildungen im Text. Price 4 marks. Berlin: Verlag von August Hirschwald, 1911.

This monograph of ninety pages is a reprint of a paper in the *Archiv für klinische Chirurgie*. It consists of numerous clinical histories of gastric disease, with the laboratory findings and with retouched x-ray photographs. Schmieden's conclusion is that neither chemical analysis nor x-ray pictures alone should be held sufficient in attempting the diagnosis of gastric disease, especially of ulcer or cancer; both should be used in every case, as their results amplify and correct each other.

Diagnostik und Therapie der Magenkrankheiten. Von Prof. Dr. T. Boas. Sixth Edition. Price 17 marks. Leipzig: Georg Thieme, 1911.

The present book on diseases of the stomach appears in its sixth edition and is the work of one of the greatest specialists in this field, Professor Boas. As a textbook it stood the test of time for the last fifteen years and was found to be extremely practical and useful. In the present edition the value of occult blood in the diagnosis of digestive diseases, first described by Boas, naturally occupies a prominent position. The Rontgenology of the stomach and gastroscopy are also given prominent places. According to Boas, examinations of the stomach in the fasting condition are of great import. A normal stomach should be empty; if quantities of food, microscopically visible, are found there is some distinct disturbance with the motor function of the stomach. If there is no food, but gastric juice in considerable quantity present (over two ounces), we have to deal with hypersecretion. The latter may be of neurotic origin or due to an open ulcer near the pylorus. In the dietetic treatment of hyperchlorhydria the author lays much stress on the prescribing of fats in abundance. This group of nourishment, as is well known, tends to diminish gastric secretion and thus reduces the acidity. In malignant diseases of the stomach Boas advocates early operation, provided there is some hope of total resection of the tumor. Within the last three years there were among the total resections of the growths 18 per cent without recurrences. Boas' book needs no further recommendation. It will find a prominent place in every practitioner's library.

Die Gastroskopie. Von Dr. Hans Elsner. Price 8 marks. Leipzig: Georg Thieme, 1911.

This is a monograph on an entirely new subject, namely, "Gastroscopy." The author gives his experiences for five years with this new and important method of examination. Gastroscopic examination may only be done in patients with an empty stomach, since all stomach contents impair the transparency and purity of the prism or the objective. Lavage of the stomach even before gastroscopy is not desirable. The wash water, some of which always remains in the stomach, forms air bubbles when air is pumped into the stomach; this either obscures the view entirely or veils it more or less. In preparing a patient for gastroscopy Elsner makes use of anesthesia, both general and local. Twenty to thirty minutes before examination the patient is injected with gr. 1/6 or preferably gr. 1/3 of morphine muriate. Just as important as this general narcotic during the first gastroscopic examination is the local application of cocaine. A small swab of cotton attached to a Krause forceps is dipped into a 10 per cent. solution of cocaine. The cocainization takes place in three stages: First, the base of the tongue, the uvula, and the anterior pillars are touched; then the posterior pillars, pharynx, and sinus pyriformis are cocainized. Finally the lowest part of the pharynx and the entrance to the esophagus are cocainized in the following manner. The cotton swab is placed between the arytenoid cartilage and posterior pharyngeal wall and then, on deglutition, inserted into the esophagus as far as possible. Cocainization of the epiglottis, sinus pyriformis, and arytenoid cartilages with the assistance of the laryngoscope has been superfluous in most cases. In especially sensitive patients it is, however, advisable to use it. Cocainization should as a rule not take longer than four to five minutes. A few minutes later, after loosening the clothes, we can proceed to the examination. The position of the patient must be one in which the natural obstacles to the introduction of the straight gastroscope are overcome as much as possible. In other words, we must try by proper position of the patient to straighten out as much as possible the physiological bends of the esophageal tube in order to make the introduction of the gastroscope possible or easier. The lateral position, with face turned slightly downward, probably is the best for this purpose. In this position the muscles of the neck are relaxed and the lower part of the esophagus is sufficiently straightened out so that the instrument slides into the stomach without resistance. The lateral position with face turned downward also has the advantage that all saliva and mucus, which during the examination are often secreted in abundance, can easily flow out of the mouth. Coughing and swallowing caused by the mucus collected above the entrance to the larynx are less in this position or may be entirely absent. Further advantages of the lateral position are in the inspection of the stomach itself. The posterior wall, hard to see in the dorsal position, is usually easily inspected in the lateral position. The same may be said of the pylorus. As a rule, Elsner first introduces the gastroscope in the left lateral position. The left leg is kept extended and the right, bent at the knee, laid over it. The head of the patient lies in the hands of an assistant who bends it backward. The assistant must follow every motion of the examiner. Where an assistant is not at hand a cushion may support the head of the patient. Then with the left hand the head must be bent back while trying to make a straight path for the introduction of the tube. Elsner's work on gastroscopy is timely and can be recommended in the highest terms.

Electricity: Its Medical and Surgical Applications, Including Radiotherapy and Phototherapy. By Charles S. Potts, M.D., Professor of Neurology, Medico-Chirurgical College; formerly Instructor in Electrotherapeutics and Associate in Neurology, University of Pennsylvania Medical Department. With a Section on Electrophysics by Horace Clark Richards, Ph.D., Professor of Mathematical Physics in the University of Pennsylvania, and a Section on *X*-Rays by Henry K. Pancoast, M.D., Professor of Röntgenology in the University of Pennsylvania, Medical Department, Philadelphia. With 356 illustrations and 6 plates. Price $4.75 net. Philadelphia and New York: Lea & Febiger, 1911.

This is a remarkably comprehensive work dealing with medical and surgical electricity. As the author points out, for the intelligent use of electricity as a remedial agent a knowledge of the changes in the tissues and functions of the various organs of the body caused by its passage is essential. Therefore a knowledge of what is known as electrophysiology is most important. In treating this subject Dr. Potts has adopted an original plan which consists, instead of devoting one section exclusively to the constant current, another to the static current, and so on, in grouping these modalities according to the effects produced. This seems the most rational manner of presenting this subject. The matter and arrangement of the book are both excellent, while the large number of good illustrations is a great aid to the proper comprehension of the working of the currents. The work appears to be a thorough exposition of medical and surgical electricity, and as such may be recommended to medical students and practitioners. Electrophysics and the *x*-rays are ably discussed by Drs. Richards and Pancoast and, as said before, the work is a valuable textbook.

Diseases of Infancy and Childhood. Their Dietetic, Hygienic, and Medical Treatment. A Textbook Designed for Practitioners and Students in Medicine. By Louis Fischer, M.D., Attending Physician to the Willard Parker and Riverside Hospitals of New York City; Attending Physician to the Sydenham Hospital; former Instructor in Diseases of Children at the New York Post-Graduate Medical School and Hospital, etc., etc.; Fellow of the New York Academy of Medicine. Fourth Edition. With 308 illustrations, several in colors, and 30 full-page half-tone and color plates. Price $6.50. Philadelphia: F. A. Davis Company, 1911.

If this volume is to be judged by its size it is indeed a "big" book. The author has succeeded in crowding into it a great deal of "pediatrics," including many case reports from his private and hospital practice. There is, however, lacking a proper homogeneity in the arrangement and disposition of the material. This is particularly evident in the chapters on infant feeding which, though they show many alternative methods, nevertheless in the very profusion of these methods are apt to bewilder the uninitiated reader. The author has brought the present edition strictly up to date by including such topics as casein-milk feeding, the etiology of poliomyelitis, the newer diagnostic importance in meningitis of examination of the cerebrospinal fluid, the use of the duodenal bucket, and experiences with salvarsan. The author uses the term "basilar meningitis" as synonymous with tuberculous meningitis, evidently unaware of the fact that chronic basilar meningitis has been shown by recent investigations in England to be due to a diplococcus, probably identical with that of Weichselbaum, although of less virulence, and that this form of meningitis is really a variety of cerebrospinal meningitis. In view of the widespread prevalence of poliomyelitis, the description of this disease as given in this book is too brief and unsatisfactory. The lack of proportion is exemplified in the inclusion of cyclops and the omission of arthritis deformans. The enumeration of these defects need not deter one from disregarding the many good points of this work. The infectious diseases, particularly diphtheria and scarlet fever, are fully and ably described. The illustrations are numerous and helpful. There are included in the text and appended in the back of the volume many suggestive prescriptions. The book is a practical one, original in many of its features, and shows evidence of considerable labor in its preparation.

Society Reports.

THE WESTERN SURGICAL ASSOCIATION.

Twenty-first Annual Meeting, Held at Kansas City, Missouri, December 18 and 19, 1911.

THE PRESIDENT, DR. AMOS W. ABBOTT, MINNEAPOLIS, MINNESOTA, IN THE CHAIR.

The Pathology that Remains after Nonsurgical Treatment of Inflammation within the Abdominal Cavity.—Dr. J. W. COKENOWER of Des Moines, Iowa, read a paper on this subject, in which he drew the following conclusions: (1) That pain in the abdomen is Nature's signal of distress and always means something, but should not be relieved to the extent that it will retard or prevent ascertaining the cause that produced it. (2) That infection in the abdominal cavity is not unlike infection in any other part of the body, and as soon as the diagnosis is cleared up the cause and pathology should be removed as far as possible in any way that will give the best results. (3) That the nonsurgical treatment of peritonitis is the cause of recurrent attacks of appendicitis, cholecystitis, salpingitis, and, in fact, nearly all recurrent inflammations in the abdominal cavity producing an infected pathology.

Cancer of the Hollow Viscera of the Abdomen with Special Reference to Diagnosis.—Dr. MILES F. PORTER of Fort Wayne, Indiana, reported three cases, and drew the following conclusions: (1) The symptoms commonly regarded as sufficient to warrant a diagnosis of cancer of the hollow viscera are such as are not manifest until the favorable time for surgical interference has passed. (2) Success in the treatment of cancer of the hollow viscera depends largely upon its early recognition. It is often unsafe and unwise to make a diagnosis between malignancy and benignancy without the aid of the microscope. (3) The way to improve our results in the surgical treatment of cancer of the hollow viscera lies in the direction of earlier celiotomy and immediate microscopical examination of the specimen.

DR. L. L. MCARTHUR of Chicago urged the use of the erect posture when a digital examination was being made in cases of suspected carcinoma of the rectum. He also urged the use of the sigmoidoscope, or the long rectal instrument with an electric light within its lumen at the deeper end, rather than the head mirror. The latter rarely gave an illumination that was satisfactory, whereas the little electric light within the sigmoidoscope did.

DR. JAMES E. MOORE of Minneapolis, stated that future progress must be had from making timely exploratory operations. He did not mean that these should be made by every family physician, but by men who knew pathology when they felt it and saw it. Speaking of the feeling of pathology, it was difficult sometimes to differentiate between benign and malignant growths when the surgeon had the tumor between his fingers. This was particularly true of the hollow viscera, yet he maintained that when a case was sufficiently grave to warrant exploration one was justified in taking out a piece of the growth, making a frozen section and establishing an absolute diagnosis at the time.

DR. AMOS W. ABBOTT of Minneapolis merely wished to call attention to an easy way of examining the rectum in cases of suspected carcinoma, and that was with the use of the ordinary Kelly cystoscope. One could get as good a view of the bowel with it as with the larger proctoscope under ordinary circumstances, and patients did not object to it.

DR. W. W. GRANT of Denver said the fact that the surgeon knew nothing of these cases, had not had the opportunity for any examination until the disease was far enough advanced to produce distinct clinical symptoms, often showed that it was too late even then to predict a good result from operative interference. As our instruments of scientific precision were at the present time indefinite and uncertain, we must get a closer study of the clinical history of these cases by the physician, and until that time came and we had better diagnosticians and better clinicians, we would perhaps not have earlier diagnoses and better results in the treatment of cancer of the hollow viscera.

DR. JAMES F. PERCY of Galesburg, Ill., said the essayist had suggested that if he could have recognized the ulcer that was bleeding and had done a posterior gastroenterostomy, he might have saved his patient. The speaker had had a similar experience to that reported by the essayist in which he resorted to posterior gastroenterostomy. The ulcer was in the pylorus. An attempt was made to close it up by adhesions to the liver. His patient did well for four or five days, and was apparently making a good recovery, when he had a profuse hemorrhage, vomited two or three basinsful of blood, and died. The speaker questioned whether gastroenterostomy was going to save many patients who had large ulcers.

DR. M. L. HARRIS of Chicago said that until some specific reaction was discovered, the diagnosis of cancer in all internal organs, those not subjected to direct investigation by the microscope in their inception, was entirely one of probability.

DR. PORTER, in closing, said that when one made an exploratory operation in cases of suspected cancer, as was done now in connection with the appendix, satisfactory results would be achieved.

The Early Removal of Gallstones, and the Preservation of the Gall-Bladder as a Preventive of Disease of This and Contiguous Organs.—Dr. ARTHUR E. BENJAMIN of Minneapolis, Minn., drew the following conclusions: (1) Gallstones are not normal residents of the gall-bladder. (2) They are the products of infection from the alimentary canal and a late complication of the microbic invasion of the gall-bladder. (3) Many of the severe gastrointestinal symptoms are due to the presence of gallstones lodged in the biliary tract. (4) Cholecystitis resulting in the production of gallstones will recover less rapidly when stones are present. (5) Whenever stones can be diagnosed an operation should be advised. (6) Gallstones often migrate from the gall-bladder to the cystic or common duct and later lodge there, causing destruction of tissue and obstruction of the ducts. The operative mortality is 3 per cent. when in the gall-bladder and 11 per cent. when in the common duct. (7) Inasmuch as an operation for gallstones is usually one of "terminal events," an operation should be performed if possible before they are found, namely, in the cholecystitis period. (8) The interdependence of the gall-bladder, stomach, liver, and pancreas is such that the gall-bladder should be preserved in all cases where it is not hopelessly diseased and unable to regain its function. (9) The frequency with which pancreatitis is associated with gallstones in the common duct makes the gall-bladder an essential organ to assist in the drainage of the biliary passages in pancreatitis, and should be saved. (10) The percentage of cancer associated with and following the irritation of gallstones in the biliary tract should urge all practitioners to recognize their responsibility in a case of postponed operation for gallstones.

Further Advances in the Therapeutic Utilization of the Bile Tracts.—Dr. LEWIS L. MCARTHUR of Chicago stated that in practically every operation for bile tract disease the operator established a temporary biliary fistula, either in the gallbladder or common duct, for the purpose of relieving the cholemia, the cholangitis, or cholecystitis, by continuous drainage, in much the same way as a urinary cystitis was relieved. While flushing such fis-

tulæ for the purpose of lavage of the gall-bladder, it was noted that the irrigating fluid frequently failed to return. This suggested the idea of utilizing these fistulæ for purposes of rapid hydration, of systemic medication, of feeding, and stimulation. The results were so startling and so gratifying that he felt justified in asking others to try it. With the refinements in technique proposed by Dr. Matas the procedure recommended was as follows: If through a tube draining the gall-bladder in an ordinary case of cholecystostomy we connected the tube of an irrigator containing, for example, sterile warm normal salt solution, the rate of flow being graduated so as not to exceed five or six drops per second, and the pressure to be no more than 20 inches elevation, a continuous flow in the duodenum could be established and maintained without discomfort to the patient. At that time he had refrained from using the irrigation through the tube introduced for drainage of the common duct until the second or third day; that was, till walled off from the general abdominal cavity for fear of leakage. Here was where Matas had shown an improved technique, as well as how safe and efficient was the introduction at the time of operation of a smaller rubber catheter (*à demeure*) into the duodenum by way of the common duct, letting it project there one-third or to one-half its length. Through this, with absolute confidence of its arriving safely within the duodenum, he could introduce any desired amount of any given fluid, food or medicament indicated. In fact, he had in this manner for a period of three weeks given diuretin, a beef preparation, strychnine, castor oil, and mineral waters in purgative doses to the great satisfaction of the patient and with no untoward results because of the method of introduction.

Dr. Van Buren Knott of Sioux City, Ia., said that, with reference to Dr. Benjamin's paper, he regarded the statistics of the percentage of cases of pancreatitis as complicating gallstones to be unreliable. Pancreatitis was a condition which we were not at all times able to determine. He had been much interested in Dr. McArthur's work on the gall-bladder. He had been following some of his suggestions with beneficial results, using the common duct as a means of furnishing fluids and nutriment to the patient.

Dr. Arthur T. Mann of Minneapolis said it was "up to" the surgeon to make an early diagnosis of gallstones. The diagnosis we made now was not one of the presence of gallstones, but a diagnosis based upon the complications of gallstones. The characteristic pain, nausea and vomiting, and inflammation around the gall-bladder were all late manifestations of gallstones, and not early ones, and he thought we had to direct our attention, as we did to appendicitis twenty years ago, in making a diagnosis of appendicitis when there was an abscess, when there was a peritonitis, and so on, and it was the same way with gallstones. We had to take a step in advance and make the diagnosis when the gallstones were forming. The symptoms of the early presence or early formation of gallstones were very obscure. This had to be worked out as was done with appendicitis. The symptoms were not in the gall-bladder, but in the stomach.

Some Phases of the Surgical Treatment of Gastric Ulcer.—Dr. W. D. Haines of Cincinnati, Ohio, said that one of the principal phases of the surgical treatment of gastric ulcer was the adoption of some plan which would effectively relieve the distress of the patient, free him from the handicap of ulcer symptoms in his wage-earning capacity, and diminish his chances of becoming a subject of cancer of the stomach. In a limited experience with the recurrence of symptoms after operation for gastric ulcer he was wholly unable to distinguish at the time of operation the type of ulcer which would be cured and remain cured by a gastrojejunostomy from the type to which this operation would afford but brief relief from ulcer symptoms. Removal of the ulcer-bearing area, as recommended by Rodman, while in many respects an ideal operation, carried a prohibitive mortality and had not been generally accepted by the profession as the best method for dealing with gastric ulcer. Excision of the individual ulcer in conjunction with gastroduodenostomy or gastrojejunostomy was an operation which was rapidly gaining favor with American surgeons. Excision had many commendable features—it was applicable to a solitary ulcer situated in any part of the stomach wall, it added very little to the risk, and the end results were more satisfactory. Due weight should be given the physical condition of the individual case before determining upon the type of operation to be performed. Some of these ulcer cases were much reduced in weight and their powers of resistance were greatly enfeebled in consequence of long physical suffering, poor nourishment, and mental depression. This class of cases taxed the ingenuity of the experienced and their successful management and contributed a large percentage to the death list in the surgical treatment of gastric ulcer. The rapidity with which some of these half-starved ulcer cases recuperated after efficient stomach drainage was established had enabled him to convert in a short space of time an almost helpless risk into a comparatively safe risk for a secondary or causal operation, excision—resection of the ulcer-bearing area. Rarely indeed had he seen a case of chronic gastric ulcer which did not show some degree of gall-bladder or pancreatic involvement. With a view of relieving this phase of gastric ulcer pathology Dr. S. H. Smith and he had for the past two and a half years been draining the gall-bladder in connection with the work on the stomach. The immediate results had been very gratifying, and the after history of those cases which they had been able to trace had derived permanent benefit from this additional procedure, such as to warrant further continuance of this practice.

Dr. James F. Percy of Galesburg said the essayist spoke about drainage operations in stomach surgery. Recent work had shown that none of these operations were drainage operations in the ordinary sense. If one made a hole in the bottom of the stomach and attached the bowel to it the mechanical processes of digestion would go on just the same. In other words, the organ did not empty itself until a certain number of minutes or hours after the food was put in there. One merely switched the pylorus, but it was not a drainage operation in the strict sense. One might relieve the so-called pyloric area from irritation and in that way produce benefit. But back of all of this was the great question, what caused gastric ulcer? None of our recent literature threw any light on that question. As the essayist had said, the gall-bladder might be back of a lot of these infections. Other men had told us that the appendix was the cause of these lesions, but we were not absolutely sure. One of the saddest chapters, if it were written, and perhaps never would be written, was the neurotic side of stomach surgery. If a case had a neurotic basis it was more important than anything else in determining operation unless there was some gross lesion that any practitioner could diagnose.

Dr. Van Buren Knott of Sioux City, Ia., said that a few years ago we were taught that the main indication in the treatment of gastric ulcer was to reestablish gastric drainage; that if the stomach was properly drained by gastroenterostomy, made at the lowest point of the stomach, the drainage being more or less perfect, the symptoms of distress incident to the ulcer would disappear. We now knew that this was fallacious. Drainage of the stomach at the lowest point did not necessarily relieve the condition of ulcer. It had been said that gastroenterostomy made proximal to the pylorus or ulcerated area would re-

heve the ulcer from the irritation due to or incident to the efforts of the stomach to carry on its part of digestion, but this was not true. If a gastroenterostomy was made the food would go to the pyloric end of the stomach, irritate the ulcer on the way back through the peristaltic waves, so it did not accomplish what was thought in removing the irritation from the diseased area. The treatment of ulcer of the stomach must be based on more logical grounds in the future than in the past. Ulcer of the stomach should be treated the same as a diseased area anywhere else, and that was by removal if possible.

Dr. L. L. McArthur of Chicago pointed out that internists had in the last four or five years led surgeons to disconnect some of the gastroenterostomies that had been done for stomach ulcer, in which cases the diagnosis was all right and the treatment apparently the recognized treatment, but there was a failure in results. For what reason? The motility of the stomach was perfect, or nearly so, and when a gastroenterostomy was made in the stomach in which the motility was normal, the food went out from the pylorus, and many observers, notably Dr. William J. Mayo, had found that the gastroenterostomy opening closed or became so narrow that function was interfered with, but as long as the pyloric opening was good and efficient, and the motility of the stomach was good, function went on. Therefore, before resorting to operation for gastric ulcer it was not only important to determine the acidity of the stomach and its capacity for the Ewald meal and the motor meal, but if the motility of the stomach was good a gastroenterostomy would be efficient.

Dr. Haines, in closing, stated that his paper was written merely for the purpose of driving home the argument that the test meal, as it was used to-day, was an artificial process pure and simple. In other words, the influence of the mind upon the secretion of the stomach was just the same as it was upon the secretion of the kidney or the mammary gland or any other glandular tissue in the body. We must seek the real cause of the symptoms. Surgeons had been operating upon the stomach when they should have been looking at the right tube or appendix, the right kidney, the duodenum, the gall-bladder, etc.

Fibrous Tuberculosis of the Peritoneum Involving Omentum, Intestine, and Uterus.—Dr. C. Lester Hall of Kansas City, Mo., stated that the interesting feature in connection with his case was the unusual size of the nodules, varying from that of a mustard seed to a small hazelnut, which were not simply implanted on the tissues, but were buried down in the omentum and mesentery, making it impossible to remove them without tearing into the bowel. Recovery from the operation was uneventful, and to-day, twelve months after the operation, the patient reported herself in fair health and physical condition.

End Results in Gallbladder Surgery.—Dr. B. B. Davis of Omaha said that by correspondence and by personal examinations and interviews he had been able to gain a fair knowledge of the postoperative condition of 234 cases for periods ranging from six months to twelve years following operations. Of this number there were 60 males and 174 females, or approximately 3 females to 1 male. Of the 234 gall-bladders of which a record was made, 150 contained stones, and 84 were cases of cholecystitis, acute or chronic, without stones. At the primary operation 176 were drained, and 58 were subjected to cholecystectomy. Only 1 of the 58 cases on whom cholecystectomy was done primarily had had enough postoperative trouble to require relief by secondary operation, and this was done to break up adhesions that were interfering with the emptying of the stomach. Relief was complete eighteen months after the operation. Of the 176 cases of primary drainage 11 had been such sufferers as to be willing to have another operation performed. The second operation in 10 of these cases was cholecystectomy with relief finally in all of them, but at least 2 of these continued to have considerable pain for several months. One of the cases operated upon a second time did not seem to show sufficient cause for cholecystectomy and a drainage operation was done. The relief was only partial. Aside from the 11 cases operated upon secondarily for unrelieved or recurrent symptoms, 5 had been readmitted to the hospital for medical and massage treatment without operation. Two of these patients were relieved by the hospital treatment and 2 received no benefit and were still suffering. The fifth case had been back twice and each time rest, hot packs, Carlsbad salts, careful diet and light massage had given relief. His last stay in the hospital was only three months ago, and it was agreed that if the symptoms returned he would come back for a cholecystectomy. Besides the 5 cases just mentioned that returned to the hospital for treatment, he had records of 12 other cases that complained greatly for a time, but as far as it had been possible to ascertain, most of them were better, and at least 7 were completely relieved. His records in regard to persistent fistulæ were incomplete, but several had not closed for from three months to six months after operation. One of these was still discharging, almost a year after he left the hospital, but as there was no pain and the general health was excellent, the woman would not consent to another operation. As nearly as it had been possible to learn from the postoperative history of his cases an encouragingly large number were practically relieved immediately and completely as soon as they recovered from the operation.

(*To be continued.*)

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, December 18, 1911

The President, Dr. Reynold Webb Wilcox, in the Chair

Presentation of a Patient on Whom Lipotomy Abdominis Was Performed.—Dr. Edward Wallace Lee presented this patient, a woman of 45, from whom he had removed, by operation, a large amount of abdominal fat. Previously, the accumulation of adipose tissue, he said, had been so enormous that she was unable to perform her ordinary household duties, the abdomen being pendulous and reaching half-way down to her knees. On May 3, 1911, he removed a large section by means of a semicircular incision, 36 inches long, extending across the abdomen; the fat thus withdrawn amounting to fifteen pounds. In addition, he removed some by curetting, and later between four and six pounds of liquid fat oozed away through drainage tubes which he had inserted. There was absolutely no suppuration or any evidence of sepsis, and the patient left the hospital at the end of three weeks. While she was still very stout, the operation had been successful in restoring her to a condition of complete comfort.

Amputation of the Thigh for Gangrene: Presentation of the Patient.—Dr. J. Herman Branth presented this patient, a sea-captain, 68 years old, in excellent health, stating that he was called to see the man in consultation on January 5, 1911, at Milford, Conn. He was suffering intense pain in the left foot, and on the upper surface of the second and third toes was a faint bluish discoloration. The foot and leg were cold, and no pulsation could be felt in the leg. The general temperature was 101° F., and the radial pulse rapid, soft, and intermittent. The diagnosis made by Dr. Branth was occlusion of vessels, with approaching gangrene. Senile gangrene was thought improbable, on account of the robust appearance of the patient, and careful urinary analyses excluded diabetes and renal disease, while there was no alcoholic habit. Frost-

bite was considered, but such a history was denied. Subsequently, however, the patient admitted that he had sat for a long time playing cards one cold night in a summer cottage, where the only heat was furnished by a kerosene stove. Before retiring he immersed his chilled feet in a vessel of hot water, and the sudden change of temperature from somewhere below freezing point to 120°, or more, no doubt caused coagulation of blood in the vessels. All that could be done for the time being was to stimulate the heart, improve nutrition, control pain with opiates, and await Nature's demarcation between the dead and living tissues. In this instance, however, the line of demarcation never became positively definite. The entire foot grew black, as well as the tibial region up to two inches below the attachment of the patellar ligament, and also the peroneal side of the leg. The calf looked white to half-way down the leg, and the soft tissues near the tibia and fibula were now liquefying. On February 20 the patient was taken to the Bridgeport Hospital for operation. The proximity of the lesion to the knee-joint (inflammation in which would no doubt have resulted fatally) suggested the propriety of a thigh amputation, which was performed on February 25. Femoral myelitis and aneurysm of the femoral and popliteal arteries were not suspected, but as these were discovered at the operation to be present (probably as the result of the conditions in the limb below), it was found necessary to make a second amputation several inches higher, at the junction of the upper and middle thirds, in order to get above the infected marrow and the femoral aneurysm. After the femur had been sawed off the second time the marrow was cleaned out with the finger for about an inch further up and a blood-cast, perhaps five inches in length, was removed from the femoral artery. Dr. Branth described his operation for amputation of the thigh as follows: The anterior flap is composed of the quadriceps extensor muscles and the posterior flap of the adductor and abductor muscles, and these are stitched together (anterior to posterior) over the bone stump. The fatty tissue and skin are sutured in a separate layer, all with the Pagenstecher ligature. The sciatic nerve is cut short, and the two small arteries in the nerve-sheath ligated, so that no blood-clot can surround and compress the nerve-end and form an organized clot to develop amputation neuralgia, a condition often giving rise to pain and cramps which are felt by the patient just as if the limb had not been removed. The aneurysms in the femoral and popliteal arteries were not composed of layers, and each had a channel for the blood current. The former was the size of a hen's egg and contained a clot resembling brown putty, and the popliteal aneurysm was fusiform in outline. The amputated limb was black, and with the foot withered. The anterior tibial and fibular regions were semi-liquid, and the muscular tissue, on section, was of a gelatinous consistence. The calf was a mere shell of skin, holding together the putrid mass. After the operation the patient suffered from shock, which was met by the usual remedies. He soon developed a good appetite, and by the end of the first week was allowed full diet. On March 5 the dressing was removed. The wound was dry and aseptic (with not even a stitch abscess), a result which spoke well for the high degree of asepsis maintained during the operation, and one due also, the speaker believed, to the fact that the saw was kept cool by means of a stream of water, so that the heat produced by friction could not injure the bone. In addition, the highly successful result was attributed to a considerable extent to the flushing of the wound surface with water at a temperature of 120°, poured from a pitcher, for the purpose of removing bone dust and any other loose particles. The stump was also thoroughly sponged off with the hot water before the application of the dressing. At the removal of the first dressing two drainage tubes, which had been employed, were taken out and a new dressing was then applied. On March 9 the patient was able to wheel himself in a wheel chair through the halls and into the smoking room. The remaining stitches were removed on March 12, and the recovery was rapid and without any interruption. In amputation of the thigh, Dr. Branth went on to say, the mortality, which ranged from 30 per cent. to 80 per cent., increased in proportion to the nearness of its site to the trunk. Age was a factor, and amputation for injury had a higher mortality than that for disease. Years ago there was brought to the hospital a young man of 22 whose leg had been run over by a locomotive and crushed from the condyles down. There was little hemorrhage until he was laid on the bed in the ward, when the popliteal artery began to spout. The patient was smiling and talkative, though somewhat dazed. Dr. Branth cut away the debris, sawed off the femur above the condyles, and secured the vessels, but before the dressing was completed the patient suddenly expired.

Dr. WILLIAM STEVENS said he had had the opportunity of being present at Dr. Branth's amputation of the thigh. Hot water (at 120°) was used very freely, and, in his opinion, the excellent result that had been met with was principally due to this fact. There was no pus and no discomfort to the patient.

Dr. MORRIS said he would like to inquire whether in the case of the young man who died suddenly the pulse could be felt. Usually in cases of this kind, although the patient might even be telling funny stories, the pulse could not be felt.

Dr. Branth again emphasized the value of hot water in amputation cases, saying that it tended to prevent sepsis and formed a sort of glue which facilitated primary union. In his case the leg-maker had assured him that the stump was well shaped for the employment of an artificial limb. In many instances this was not the case, but here the conditions were satisfactory, the posterior flap, which had to bear the brunt of the pressure, being thicker than the anterior. As to the case of sudden death, this occurred over thirty-five years ago, and he could not now speak positively as to the condition of the pulse. His attention naturally, was principally devoted to checking the hemorrhage.

Gastric Symptoms in Biliary Disease.—Dr. HOWARD LILIENTHAL said that in the treatment of several hundred cases of gall-bladder disease during the past nine years he had received the impression that about 80 per cent. of them had been treated for some form of gastric disturbance, and that the gall-bladder had not been suspected until a sudden obstruction or an acute invasion made the true character of the case clear. That there was an interdependence of symptoms between the two organs could not be doubted, and that in biliary disease the stomach was affected, both as to its motility and chemistry, was certainly observed very frequently. From his own observations he was pretty well convinced that digestion was more often disturbed by the presence of infection or calculi in the bile passages, rather than that as a rule the gastric disease antedated and was partly responsible for the biliary disturbance; and, indeed, he was inclined to agree with Dickinson, who had suggested that the constant pouring of infection into the portal system from a chronically diseased appendix would account for much gall-bladder disease. Roughly speaking, the cases of the latter coming to operation might be divided into the chronic and the acute. In the chronic, even though an acute cholecystitis occurred, it was very frequently not diagnosed as such, or, if recognized, was thought to be a new development; and not until the suffering dyspeptic was permanently relieved, as the result of an operation upon the gall-bladder, was the truth suspected.

Case I.—This was illustrated in the case of a married woman, 35 years old, who had been treated for many years for dyspepsia. Dr. Lilienthal was called to see her by two physicians, in consequence of an acute febrile attack, with the sudden appearance of a tender mass in the right hypochondrium, extending below the level of the umbilicus. Although there was no jaundice, the history of the case, together with the feel and shape of the tumor, made it seem as typical a case of cholecystitis as could be found. He assumed that both gentlemen were aware of the probable diagnosis, and advised an immediate operation, but to his astonishment this seemed to come to them as a complete surprise. He had no doubt, however, that had this patient come to either of them as a new case, a prompt and correct diagnosis would have been made. The patient was operated on the same day and relieved of a large, tense, suppurating gall-bladder.

Case II. was that of a woman 60 years of age, who had been treated by an eminent specialist for indigestion due to a perversion of gastric secretion. After some weeks she began to be more acutely ill, vomiting several times a day. Finally, the vomitus having become brownish and with a foul odor, and the abdomen having become somewhat distended, another physician was called in, who, recognizing a surgical disease, summoned Dr. Lilienthal. Intestinal obstruction, due to some lesion of the right iliac fossa, where the sensitiveness was a little more marked, necessitated an immediate operation; when, to his surprise, an enormous gallstone, completely obstructing the ileum, was encountered and removed. He closed the intestinal wound with suture and the patient made a prompt recovery. Indigestion, with repeated attacks of pain and belching, or even no pain but severe discomfort, particularly after eating meat, should, in the absence of emaciation and jaundice, arouse a suspicion of gall-bladder stone of large size. Small stones were apt to pass into the common duct, thus causing more or less icterus. The increase in weight in biliary disease, more particularly when gallstones were present, had been an interesting observation. Long-continued jaundice, however, tended to cause emaciation. The typical gall-bladder patient was a woman in the early forties who had rapidly taken on flesh, who ate ravenously, bolting her food, and who was careless regarding her bowels. If one added to this a nervous disposition, with frequent emotional crises, the picture would be pretty complete. In regard to the relations between gall-bladder and appendix, he had become so convinced of the frequent coincidence of these disorders that he invariably questioned the patient, with a view to bringing out the history of a possible old appendicitis. If there was a working suspicion of this diagnosis he usually removed the appendix through a second small incision at the time of the operation on the gall-bladder, and even if the history were negative he tried to draw the cecum into the upper wound, in order to examine the appendix before completing the operation.

Case III, that of a woman of 31, illustrated the usual type of pure gall-bladder calculi without infection and with no calculus in other parts of the body. She was sent to him with a diagnosis of cholelithiasis, and he went so far as to further suggest the probability of one or more large stones, and no small ones, because there had never been the slightest jaundice. This proved to be correct, for at the operation a rather thin-walled gall-bladder, containing a single large ovoid calculus, was found and removed. Some years later he operated upon the same patient for calculus in the renal pelvis, this being one of perhaps half a dozen cases in which he had met with the coexistence of biliary and renal calculus.

Case IV. was one of infection of gall-bladder and appendix in a female patient of 42. At operation there was found a chronic appendicitis, the organ being high up under the gall-bladder, the walls of which were also very tense and thick. There were no gallstones, and the tension was doubtless due to numerous old adhesions about the cystic duct, probably from old pericholecystitis. Both appendix and gall-bladder were removed, and the patient was completely relieved of the dyspeptic symptoms from which she had suffered for many years.

Case V. that of a woman of 40, presented the same association of lesions. On incision a large calculus, with a thick-walled gall-bladder full of muco-pus, was found and removed, and the appendix, which was very large and subacutely inflamed, was extracted through the cholecystectomy incision.

Case VI was of special interest because it typified the association of cholecystitis with gastric symptoms. The patient, an unmarried woman of 40, had always had "stomach trouble," with one attack diagnosed as appendicitis during childhood. For twenty years she had had numerous attacks of unconsciousness, followed by profound shock, and at such times her hands invariably went to the epigastric region, a little to the right side. She was in the habit of vomiting, and a week before she came under observation the vomitus contained some blood. Physical examination was negative, but, exploration of the right upper quadrant having been determined upon, a rather thick-walled gall-bladder, with extreme stricture of the cystic duct, was found and removed. She made an uneventful recovery, and the stomach trouble, as well as the attacks of unconsciousness which had rendered her an invalid, disappeared permanently.

The speaker said he did not wish to convey the impression that all gastric symptoms meant gall-bladder disease. He met with a considerable number of operative cases in which the diagnosis of gastric ulcer or gastric carcinoma was confirmed, and it occasionally happened that when he had expected to find gallstones he encountered a gastric ulcer. Having narrated an instance of this, he said that the object of the paper was to call attention once more to the importance of considering the probability of biliary surgical disease in all cases of chronic indigestion, or at least in all which persisted for years in spite of skilful medical treatment. If we were to restore to health these unhappy "dyspeptics" we should not feel that it was a confession of weakness to advise an operation. Pure exploration, with negative findings and no improvement, did occur sometimes, but it was rare. Ulcer or cancer of stomach or duodenum, appendicitis, or adhesions were found commonly enough, but by far the greater number of the cases operated upon for gastric symptoms were in reality instances of biliary disease. His object would have been attained if he had so emphasized his subject that surgery would be called in as a legitimate source of relief a little earlier than was now the custom with the great mass of the profession, and not merely as a last resort to record the failure of pure medicine.

The Neurotic Element in Abdominal Surgery.—Dr. Morris made an extemporaneous address on this subject, and in it gave a warning against unnecessary operations. He said that if neurotic conditions had been properly considered, the discredit which fell upon ovariotomy some years ago might have been avoided.

Dr. Clarence A. McWilliams said that Dr Lilienthal's paper was certainly very timely An interesting point was, What caused the pain in gastric diseases? A well-known gastroenterologist with whom he had conversed on the subject expressed the opinion that this was due to pyloric obstruction. Thus, in a patient suffering from hyperacidity the resulting reflex spasm caused obstruction of the pylorus and, consequently, distention of the stomach; and this gave rise to the pain present. He believed it had been demonstrated that the walls of the stomach did not have any sensory nerves. So, in chronic appendicitis, as well

as in gallstone disease, we were now recognizing that many of the stomach symptoms were really due to spasm of the pylorus. As to the cause of hyperacidity, Deaver contended that this was a reflex manifestation referable to some organic change in the vicinity, as in the gall-bladder or the appendix, or to a gastric ulcer. Many of these cases were in fact surgical, rather than medical, in character. This was certainly true of many cases of gastric ulcer. He would like to inquire of Dr. Lilienthal how he would differentiate between biliary and gastric disease where the characteristic frank colics were absent. Not long since he had met with a case of perforating ulcer of the pylorus which had been treated by a physician of great ability for neurosis of the stomach. He then referred to a case of supposed gastric ulcer, in which prolonged medical treatment, including rectal feeding, proved ineffectual and operation became necessary, and this revealed a large gallstone. In conclusion, Dr. McWilliams expressed the opinion that patients with intractable stomach symptoms were becoming more and more surgical.

Dr. Victor A. Robertson spoke of the bad effect which cholecystitis was liable to have on pregnant women. Some years ago, he said, a pregnant woman came under his care who had such severe vomiting that at last he was obliged to empty the uterus. In a subsequent pregnancy the vomiting again became so pronounced that the uterus had to be emptied as before; but at neither of these times, although cholecystitis was suspected, could any evidence of its presence be discovered by physical examination. Less than a year later the patient went to Florida, and while there had a typical attack of hepatic colic and hurried home. She was not pregnant at this time, and physical examination showed an easily palpable and enlarged gall-bladder. On operation three large stones were removed, one of which was blocking the cystic duct. She then got rapidly well, and in the past two years had gained forty pounds in weight. Was it possible, he asked, that the added toxemia of pregnancy overburdened a system somewhat habituated to the toxic influence of cholecystitis, and caused an exacerbation of the patient's symptoms, which were only those of a moderate dyspepsia when she was not pregnant? This possible cause of vomiting in pregnancy was worthy of consideration in cases which were of a pernicious type. In the class of neurotic cases cited by Dr. Morris he had met with several. One notable one was that of a woman who came to him with dyspeptic symptoms. She was an indicanuric patient, with foul stools, and a physical examination was negative except for some tenderness, not marked, at McBurney's point. He made the diagnosis of chronic appendicitis and advised operation. Being dissatisfied, she consulted several specialists in gastroenterology, all of whom diagnosed cholecystitis and advised operation. Finally, she came back to him, and he called in two consultants, one of whom pronounced for gall-bladder inflammation and the other for appendicitis. It was then determined to operate, but when the abdomen was opened no biliary trouble was found, while palpation of the stomach and duodenum was also negative. As the appendix was slightly bound by adhesions, it was removed, and for six months the patient did perfectly well. Recently, however, Dr. Robertson had been hastily summoned to see her again, her pain, vomiting, and other symptoms having reappeared. This patient was highly neurotic, and the frequent examinations and questioning by physicians had undoubtedly given her the obsession of pain in the hepatic region.

Dr. Robert T. Morris said the time had arrived when we could discuss the principles of such interdependence of conditions as Dr. Lilienthal had described. He agreed with Dr. Lilienthal that not only the motility but also the chemistry of the stomach was disturbed simultaneously was infections of the gall-bladder. The liver was the great sewage disposal plant of the system. When toxins and bacteria were being poured into the duodenum, there was toxic disturbance of hormone secretion, and deranged hormone secretion led to various features classified as gastric disturbance. We might have cholecystitis and ulcer of the stomach simultaneously, due to the same toxic cause, and this toxic impression became intensified when some such disease as appendicitis resulted in forcing the liver to pour out an excessive amount of toxins or of bacteria. Ordinary intestinal putrefaction gave a chronic condition in which not only the appendix, gall-bladder, and duodenum might be involved simultaneously, but also the kidneys, as bacilluria with the presence of the colon bacillus was often an accompaniment of gall-bladder and stomach disturbance from toxins. We could go further and assume that, at the same time, concretions might form in the appendix, gall-bladder, kidneys, and urinary bladder, from the conjunction of colloids with insoluble salts under the influence of toxins. Such interdependence as Dr. Lilienthal had described seemed to Dr. Morris to allow of rather simple explanation although he preferred the phrase "simultaneous involvement of organs."

Dr. Anthony Bassler said it had afforded him unusual pleasure to listen to the presentation of Dr. Morris, for the reason that it was seldom that one heard from a surgeon such a perfect clinical description of a type of cases from a medical standpoint. Undoubtedly, no kind of patients were more anxious for operations than these splanchnoptotic ones, all of whom had a marked hystero-neurasthenic element. The neurosis and toxemia, which were clinical features in the cases, should, he thought, receive more consideration from surgeons than they did. Referring to Dr. Lilienthal's contribution, he said that the diagnosis of pathological conditions of the gall-bladder in cases which gave stomach symptoms was not so difficult in a clinical way. In the frank forms of cholelithiasis, namely, those with biliary colic, jaundice, etc., the diagnosis was sufficiently easy, but the more frequent ones were those in which frank symptoms were not present, and stomach symptoms of an indefinite nature were the only ones met with. Surgeons had been aware of the commonness of gall-bladder conditions in what might be termed the stomach cases for years, and it was only recently that the gastroenterologists were awakening to them. The main fault now lay with the general practitioner, in treating cases of stomach distress without sufficient examination and analysis. During the past few years an immense amount of work had been done in the study of stomach conditions for the purpose of diagnosing gallstone disease, and also an immense amount of time, print, and paper had been wasted on it. There was no one symptom or symptom-complex in the stomach that could lead one to the diagnosis of gall-bladder diseases. Of course, if there was an anchoring of the pyloric region or duodenum from adhesions which extended to these parts from the gall-bladder, accompanied possibly with their retraction upward by reason of such adhesions, a diagnosis would be suggested. But when it came to the status of secretion, whether high or low, motility, retarded or enhanced, and the observation of the peristaltic or antiperistaltic waves, there was nothing pathognomonic. To diagnose gall-bladder conditions we must examine the abdomen from the gall-bladder side, and not from the stomach side; that is, from the right of the abdomen and not from the left. With a patient in the sitting position, and the examiner sitting back of her, the hand could be deeply sunk into the upper abdomen, under the costal margin, and the gall-bladder region palpated. As one would compare a diseased joint with a normal one, to note the difference, so one could then compare the two sides, and it was almost always found to be the case that, when

the gall-bladder was responsible for a person's illness, local pain was present upon pressure over the gall-bladder in this way, no tenderness existing, on the left side or elsewhere in the abdomen. If 10 per cent. of all autopsies showed the presence of gallstones, and only 5 per cent of persons having gallstones manifested frank symptoms, only 1/2 per cent. of all those with gallstones had definite symptoms. Now, while we might look with question on the rightfulness of the extreme deductions of Mayo, namely, that all of those with gallstones gave symptoms of some kind, there was no doubt that he was right to an extent in 9/2 per cent. of cases. Dr. Bassler said he believed in the removal of gallstones when they gave continued symptoms of distress, whether biliary or gastric, and these cases represented a large proportion of the ones the surgeons were now diagnosing and treating properly.

Dr. Lilienthal said he thought Dr. McWilliams had not quite understood him in reference to the matter of diagnosis, for in the paper he had endeavored to designate as far as possible the points to be considered. He then went on to say that every abdominal opening was in fact an exploratory operation. Beforehand, we could not in any instance pronounce positively as to the existing condition. The right upper quadrant was to be regarded in the same light as the appendix region. In an exploratory laparotomy it was very desirable to make the incision such as would enable one to find out as much as possible. By means of the high vertical incision separating the fibers of the rectus, we could examine the gall-bladder, the duodenum, the pylorus, a good part of the stomach, and the hepatic flexure of the colon. If this was not sufficient to show the seat of trouble, we could then make a small additional incision in the right iliac region, and, even were the result negative, no great harm would be likely to result. We should not try to make the preliminary diagnosis too exact. If the troublesome symptoms had lasted for years, we ought to make the incision with an open mind. It was almost never necessary to make a very large incision, and to supplement such an incision with a transverse one might involve no little danger. The subject of gall-bladder disease in pregnancy, as brought up by Dr. Robertson, was, he thought, one of extraordinary interest. The coincidence of the two was not uncommon, and cholecystitis after labor was frequent.

Pathological Society of Philadelphia

At a stated meeting held December 28 Dr. George W. Outerbridge presented a specimen of "Unusual Dilatation of the Common Gallduct." The patient had been a woman, 50 years old, with intense jaundice. Post-mortem examination disclosed a dilated gall-bladder containing serous fluid of watery appearance, together with a single ovoid mulberry calculus the size of an olive. The cystic duct was occluded. The common bile duct was dilated enormously, and the hepatic ducts to a lesser degree. The papilla of Vater was found to be the seat of malignant disease. The pancreatic ducts appeared patulous and the pancreas was somewhat indurated. Dr. John Speese presented specimens of "Papillary Cystadenoma of the Breast." This neoplasm represents about 3 per cent. of mammary tumors and in 15 per cent. of cases it becomes malignant. It usually appears as a soft growth in the vicinity of the nipple. The occurrence of infiltration and extension and the formation of adhesions indicate malignant transformation. Dr. Herman R. Allyn demonstrated a specimen of "Chronic Endocarditis Affecting All Four Valves; Subserous Cysts of the Liver." The patient had been a boy of 15 years, who had suffered from valvular disease of the heart from the age of 5 years, following attacks of various infectious diseases. Murmurs were audible from time to time over the various valvular orifices of the heart, but death occurred from intercurrent cervical adenitis. After death, in addition to the inflammatory changes in the valves at all of the orifices of the heart, and the pulmonary valve being made up of four cusps, apparent cysts were visible on the surface of the liver, but these were thought to be factitious and caused by the presence of ascitic fluid beneath the fibrous tissue covering the surface of the liver. They could be felt during life and were supposed to be the enlarged gall-bladder containing calculi. Dr. Jay F. Schamberg presented "Clinical Photographs and Microscopic Sections of Subcutaneous Syphilomata of Six Years' Duration." The patient was a colored woman with a positive Wassermann reaction presenting on her right forearm ulcerating gummata and on her left arm firm nodules beneath the surface of the skin. Histological examination of a portion of excised tissue disclosed a picture containing among other things giant cells, and resembling both that of syphilis and tuberculosis. Both tubercle bacilli and spirochetes were looked for, but not found. Dr. Robert H. Ivy read a paper entitled "Leucoplakia Buccalis, with Report of Cases." He related four cases, in all of which the tongue escaped involvement and there was no history of syphilis. Dr. K. M. Lynch presented a communication entitled "The Bacteria of the Conjunctiva." Observations were made on individuals free from any apparent disease of the eyes, including hospital resident physicians, as well as on others presenting symptoms of acute and of chronic conjunctivitis. In more than half of the healthy cases xerosis bacilli were present, and next in frequency were pneumococci. In all cases of gonorrheal conjunctivitis xerosis bacilli appeared as soon as the gonococci disappeared.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

West Virginia State Board of Health.

Charleston, July 10, 11 and 12, 1911.

ANATOMY AND EMBRYOLOGY.

1. Name the bony prominences of the elbow and the ligaments of the elbow joint.
2. Give articulations of the first cervical vertebra.
3. Where is the spleen and what are its uses?
4. Describe the two principal arteries of the forearm and tell how they form the palmar arches.
5. Of what does a vertebra consist? Name the processes and tell what their object is.
6. Describe the stomach.
7. Give a brief description of the facial nerve.
8. Name the muscles of the shoulder and arm.
9. Name the sutures and fontanelles in the fetal head.
10. Give difference in fetal and adult heart.

PHYSIOLOGY AND HISTOLOGY.

1. Mention briefly chemical and physical changes in the air and the blood caused by respiration.
2. Discuss sleep theories, naming three hypotheses.
3. Discuss the origin, function, and fate of the red blood corpuscles.
4. State in percentage ratio of weight of blood to that of body. What percentage of loss may be borne?
5. Define systolic, diastolic, and mean arterial pressure. How determined?
6. Define enzymes and discuss briefly their action.
7. Define protein, carbohydrate, and fat. Estimate their nutritive value.
8. What is bile? Discuss its physiological importance.
9. Discribe histology of a transverse section of the spinal cord at the cervical enlargement.
10. Discuss the histological structure of the blood.

MATERIA MEDICA AND THERAPEUTICS.

1. What is Materia Medica? What is Pharmacy?
2. What is opium? Give its derivatives and dose of each.
3. Give composition of Dover's powder; Fowler's solution; Lugol's solution.
4. Give five principal emetics, dose of each and method of administering.

5. Name five intestinal antiseptics.
6. Give physiological action of urotropin, its dose and method of administration.
7. What is a specific in medicine? Give examples and make therapeutic application.
8. Define anesthesia, give examples of general and local anesthetics.
9. Define pyrexia and hyperpyrexia. How would you meet these conditions?
10. What are the therapeutic indications in intestinal hemorrhage in typhoid fever?

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. Define Chemistry.
2. How many elements are there? How represented?
3. Give symbols of gold, silver, iron, lead, arsenic, potassium, mercury, calcium, and sodium.
4. Name elementary substances used in their pure state in medicine.
5. Define qualitative and quantitative analysis, with example of each.
6. What are mineral waters? Name three.
7. Define and illustrate an acid, base, and salt.
8. What is a poison? Illustrate.
9. What are evidences of death by drowning?
10. Evidences of rape?

BACTERIOLOGY AND HYGIENE.

1. Classify bacteria and give example of each.
2. Name the bacteria frequently found in soil, water, milk, and air.
3. What are toxins and antitoxins? Give example of latter.
4. What is meant by phagocytosis?
5. Describe sterilization and antisepsis.
6. How would you prepare specimen (diphtheria) to be sent to a laboratory for examination?
7. Describe pure water; how would you render it wholesome when contaminated?
8. Describe the location of well or spring in relation to privy vault or stable.
9. Describe the hygiene of a tuberculous patient.
10. Give causes of air contamination of school room and proper ventilation of same.

PRACTICE OF MEDICINE AND PEDIATRICS.

1. To what class of diseases does chorea belong? Give treatment and name important complications.
2. Give the prognosis and treatment in a case of aortic regurgitation with general arteriosclerosis.
3. Give treatment of acute endocarditis.
4. Give causes, symptoms, physical diagnosis, and treatment of acute croupous pneumonia.
5. Describe causes, tests, symptoms, and treatment of typhoid fever.
6. Diagnosis and treatment of pleuritic effusion.
7. Diagnose, treat, and give the cause of cholera infantum.
8. Write a prescription for modification of cow's milk for a child three months old.
9. What are the causes of convulsions in infants and children?
10. Give causes and treatment of summer diarrhea.

OBSTETRICS AND GYNECOLOGY.

1. What is the placenta? From what is it formed? What is its structure and what are its functions?
2. Name the bones, straits, and divisions of the obstetric pelvis.
3. What are the diameters of the pelvic outlet? How is it bounded?
4. Describe the fontanelles and their diagnostic uses.
5. What are the signs of pregnancy, probable, doubtful and certain?
6. Interstitial nephritis in a pregnant woman, how would you treat?
7. Name the diseases of the endometrium and state their effects in pregnancy.
8. Define miscarriage, abortion, and premature labor.
9. Describe Credé's method for the delivery of the placenta.
10. What care does the mother require after labor? Define the nurse's duties.

SURGERY.

1. Give the methods of controlling hemorrhage.
2. Mention the uses of iodine in modern surgery.
3. Differentiate fracture of the surgical neck of the humerus from fracture of anatomical neck of humerus.
4. Diagnose and treat carbuncle.
5. Give treatment of shock.
6. Give symptoms and treatment of cholelithiasis.
7. Diagnose and treat Colles's fracture.
8. Give symptoms and treatment of erysipelas.
9. Give symptoms and treatment of prostatic abscess.
10. Give symptoms and treatment of strangulated inguinal hernia.

SPECIAL PRACTICE.

1. Give the symptoms of infantile spastic paralysis.
2. Differentiate between epileptic and hysteroid seizures.
3. Name the causes and dangers of otorrhea.
4. In what acute disease is the ear most commonly involved, and, as a rule, what part of the general structure of the ear is first attacked?
5. Name the conjunctival diseases due to microorganisms.
6. Name four causes of iritis, and note the subjective and objective symptoms.
7. In nephritis where does the effusion of serum first appear? In cirrhosis of the liver, where? In cardiac diseases, where?
8. State the diagnostic value of a blood examination in chlorosis; appendicitis; trichinosis.
9. Give cause, symptoms, pathology, and treatment of laryngismus stridulus.
10. Give symptoms and treatment of nasal polypi.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

WEST VIRGINIA STATE BOARD OF HEALTH.

Charleston, July 10, 11 and 12, 1911.

ANATOMY AND EMBRYOLOGY.

1. The *bony prominences of the elbow* are: Internal condyle of humerus, external condyle of humerus, and olecranon process of ulna.

Ligaments of elbow joint: Anterior, posterior, internal lateral, external lateral, capsular, and orbicular.

2. First cervical vertebra articulates with the occipital bone and with the axis.

3. The spleen is situated below the diaphragm, between the diaphragm and the fundus of the stomach; it is chiefly in the posterior part of the left hypochondriac region, but it extends also into the epigastric region.

The spleen has been held to be: (1) a place where the white blood corpuscles are made; (2) a place where the red blood corpuscles are made during fetal life; (3) a place where the red blood corpuscles are destroyed; (4) the place where uric acid is made; (5) the source of an enzyme which converts the trypsinogen of the pancreas into trypsin.

4. The two principal arteries of the forearm are the radial and ulnar. See Cunningham's "Anatomy" (1909), pages 831, 834, and 836; or Gray's "Anatomy" (1910), pages 546, 650, 647, and 654.

5. *A vertebra consists of:* Body (or centrum) and neural arch; this latter consists of two pedicles, two laminæ, and seven processes. These processes are: one spinous, two transverse, and four articular. The spinous and transverse processes are for the attachment of muscles and ligaments; the articular processes are for articulation with the vertebræ immediately above and below.

6. See Cunningham's "Anatomy" (1909), page 1050; or Gray's "Anatomy" (1910), page 1270.

7. See Cunningham's "Anatomy" (1909), page 686; or Gray's "Anatomy" (1910), page 997.

8. *Muscles of the shoulder and arm:* Deltoid, subscapularis, supraspinatus, infraspinatus, teres major, teres minor, coracobrachialis, biceps, brachialis anticus, triceps, and subanconeus.

9. *Sutures of the fetal head:* Coronal, sagittal, lambdoid. *Fontanelles:* Anterior, posterior, and four unimportant ones (two at the inferior angles of the parietal bones on each side).

10. In *the fetal heart are:* (1) Direct communication between right and left auricles, by the foramen ovale; (2) the Eustachian valve, guarding the opening of the inferior vena cava into the right auricle.

PHYSIOLOGY AND HISTOLOGY.

1. Respiration causes changes in the *air*, as follows:

	EXPIRED AIR.	INSPIRED AIR.
Oxygen.....	16.6 per cent	21 per cent.
Nitrogen	79 per cent	79 per cent.
Carbon dioxide ..	4.4 per cent	0.04 per cent.
Other gases	Often present	Rare.

	EXPIRED AIR.	INSPIRED AIR.
Watery vapor	Saturated.	Variable.
Temperature	That of body.	Variable.
Volume	Diminished.	Varies.
Bacteria	None.	Always present.
Dust	None.	Always present.

Respiration causes changes in the *blood*, as follows: *Arterial* blood is red, slightly warmer, more coagulable, more uniform in composition, contains more oxygen and less carbon dioxide; *venous* blood is purple, slightly cooler, less coagulable, less uniform in composition, and contains more carbon dioxide and less oxygen.

2. "There are several hypotheses as to the causation of sleep. It has been attributed to cerebral anemia; to chemical changes in the brain cells or neurons, such as an exhaustion of their intramolecular oxygen, or an accumulation of fatigue products; to a contraction of the dendritic processes, and a consequent break in the transmission of nervous impulses; to an expansion of the neuroglial cell processes insulating the nerve cell processes, and producing the same effect; and to a purely psychological condition, namely, loss of consciousness apart from any physical or chemical change. This last explanation is simply a cloak for our ignorance. The most probable hypothesis is that of an altered metabolism of the cerebral cells dependent upon exhaustion and diminished influx of stimuli." (Allbutt's *System of Medicine.*)

3. RED BLOOD CORPUSCLES. *Origin:* Red bone marrow, liver, and spleen. *Function:* To take up oxygen from the lungs and carry it to the tissues. *Fate:* Supposed to be destroyed in the spleen, also in the liver cells.

4. The blood is said to be about one-thirteenth of the weight of the body; recently this figure has been altered to one-twentieth of the body weight. "Just what percentage of loss (of blood) may be borne by the human being has not been determined, but it is probable that a healthy individual may recover without serious difficulty from the loss of a quantity of blood amounting to as much as three per cent. of the body weight." (Howell.)

5. "The maximum pressure caused by the systole of the heart, the apex of the pulse wave, is spoken of as *systolic pressure;* the minimum pressure in the artery—that is the pressure at the end of the diastole of the heart, or the bottom of the pulse wave, is known as the *diastolic pressure.* . . . In speaking of the pressure in the blood-vessels we refer usually to what is called the *mean pressure.* It is obvious that, so far as the larger arteries are concerned, the *mean pressure* is only a convenient expression for the average pressure during a certain period. If we know at any moment the systolic and the diastolic pressure in an artery we can estimate the mean pressure with approximate accuracy by taking the arithmetical mean of the two figures." (Howell.)

Blood pressure is determined by a sphygmomanometer.

6. *Enzymes* are substances produced by living cells and which act by catalysis. The enzyme remains unchanged and exerts its activity only upon certain definite substances.

ENZYMES.	ORIGIN.	FUNCTIONS.
Ptyalin.	Saliva.	Changes starches into dextrin and sugar.
Pepsin.	Gastric juice.	Changes proteids into proteoses and peptones in an acid medium.
A curdling ferment.	Gastric juice.	Curdles the casein of milk.
Trypsin.	Pancreatic juice.	Changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin in an alkaline medium.
Amylopsin.	Pancreatic juice.	Converts starches into maltose.
Steapsin	Pancreatic juice.	Emulsifies and saponifies fats.
A curdling ferment	Pancreatic juice.	Curdles the casein of milk.
Invertin.	Succus entericus	Converts maltose into glucose.

FOOD.	FUNCTIONS.
Proteins.	
1. All substances containing nitrogen, of a composition identical with, or nearly that of albumin; proportion of N to C being nearly as 2 to 7.	Formation and repair of tissues and fluids of the body. Regulation of the absorption and utilization of oxygen. May also form fat and carbohydrate, and yield energy sometimes. In most foods the above, both animal and vegetable, are largely converted into albumoses and peptones during digestion. These perform the above functions less perfectly, or only under particular circumstances.
2. Substances containing a larger proportion of N are apparently less nutritious; proportion of N to C about 2 to 5½.	These substances appear essentially as regulators of digestion and assimilation, especially with reference to the gelatin group.
3. Extractive matters, such as are contained in the juice of the flesh.	
Carbohydrates.	
Substances containing no N, but made up of C, H and O; the O being exactly sufficient to convert all the H into H_2O.	Production of energy and animal heat by oxidation. Form fats and possibly some proteids.
Fats.	
Substances containing no N, but made up of C, H and O; the proportion of O being *less* than sufficient to convert all the H into H_2O.	Supply of fatty tissues, nutrition of nervous system; supply of energy, and animal heat by oxidation.
Salts.	Support of bony skeleton, supply of HCl for digestion, regulation of energy and nutrition.

(Notter and Firth's *Hygiene.*)

Proteins, carbohydrates, and fats are all necessary in a well-ordered diet.

8. Bile is a secretion of the liver; it contains water and solids. The latter are bile salts (sodium taurocholate and sodium glycocholate), mucin, bile pigments (bilirubin and biliverdin), cholesterin, lecithin, neutral fats, and inorganic salts (NaCl, KCl, and phosphates).

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

9. See Cunningham's "Anatomy" (1909), pages 458 and 460; or Gray's "Anatomy" (1910), pages 836 and 840.

10. The blood is composed of plasma, red corpuscles, white corpuscles, and platelets.

The *red corpuscles* are biconcave discs, about 1/3200 of an inch in diameter; they are non-nucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They contain hemoglobin.

The *white corpuscles* are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named.

There are also *platelets*, which are very small, colorless, irregular shaped bodies; they are about one-fourth the diameter of a red corpuscle. In number they vary from about 200,000 to more than 500,000 in each cubic millimeter of blood.

MATERIA MEDICA AND THERAPEUTICS.

1. *Materia medica* is the name given to the agents used in the treatment of disease.

Pharmacy is the art of preparing drugs in a suitable form, and of dispensing them.

2. *Opium* is the exudation obtained from incising the unripe capsules of the *Papaver somniferum* (white poppy).

Officia dericatives with doses: Powdered opium, gr. j; extract of opium, gr. ss; powder of ipecac and opium, gr. vijss; vinegar of opium, ℥viij; camphorated tincture of opium, ℥ij; tincture of deodorized opium, ℥viij; granulated opium, gr. jss; wine of opium, ℥viij; morphine, gr. 1/5; morphine sulphate, acetate, and hydrochloride, each, gr. 1/4; codeine, gr. 1/2; codeine sulphate and phosphate, each, gr. 1/2; apomorphine hydrochloride, gr. 1/10.

3. *Dover's Powder* is composed of ipecac, powdered opium, and sugar of milk.

Fowler's Solution is composed of arsenic trioxide, potassium bicarbonate, compound tincture of lavender, and distilled water.

Lugol's Solution is composed of iodine, potassium iodide, and distilled water.

4. *Five emetics:* Apomorphine hydrochloride, dose gr. 1/10; ipecac, dose of the fluidextract, ℥xv; tartar emetic, dose gr. 1/2; zinc sulphate, dose, gr. xv; copper sulphate, dose gr. iv. Atropin is given hypodermically; the others are administered by the mouth.

5. *Five intestinal antiseptics:* Salol, thymol, naphthol, naphthalin, and guaiacol.

6. Urotropin, when taken, is decomposed in the body, and formaldehyde is liberated and eliminated in the urine; hence it is used as a urinary (and intestinal) antiseptic, dose gr. iv, administered in water.

7. *A specific* is an agent which has a selective curative effect on a particular disease. Examples: Quinine on malaria; mercury on syphilis; diphtheria antitoxin in diphtheria.

8. *Anesthesia* is the condition characterized by loss of sensation (and in general anesthesia by loss of consciousness also). *General anesthetics:* Ether, chloroform, nitrous oxide, ethyl chloride; *local anesthetics:* Cocaine, eucaine, ethyl chloride, ether spray.

9. *Pyrexia* is fever; *hyperpyrexia* is very high fever (above 105° F.). The treatment is by antipyretics.

The following table (from Potter's "Materia Medica") gives the chief antipyretics with their manner of action. Temperature depression may be done by five different actions working upon two principal lines, viz., by:

(*a*) *Lessening heat production, by*
- (1) diminishing tissue change,
- (2) reducing the circulation.

(*b*) *Promoting heat loss, by*
- (3) dilating cutaneous vessels, thus increasing heat radiation.
- (4) promoting perspiration—its evaporation lowering the temperature.
- (5) abstracting heat from the body.

The following list of antipyretics includes a few for each of the above-named actions, to which the numbers refer in each case, viz.:

Quinine, 1.	Aconite, 2.	Antipyrin, 1, 4.
Phenol, 1.	Alcohol, 1, 3.	Antimony, 2, 4
Salicin, 1.	Nitrous ether, 3, 4.	Cold bath, 5.
Digitalis, 2.	Acetanilid, 1, 4.	Cold drinks, 5.
	Phenacetin, 1, 4.	Wet-pack, 5.

10. See French's "Practice of Medicine" (1910), page 117; or Osler's "Practice of Medicine" (1909), page 103.

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. *Chemistry* is that branch of science which treats of the composition of substances, their changes in composition and the laws governing such changes.

2. There are about eighty elements. Elements are represented by symbols.

3. *Symbols:* Gold, Au; silver, Ag; iron, Fe; lead, Pb; arsenic, As; potassium, K; mercury, Hg; calcium, Ca; sodium, Na.

4. *Elementary substances used in their pure state in medicine:* Oxygen, chlorine, iodine, sulphur, carbon, phosphorus, mercury, and iron.

5. *Qualitative analysis* is the determination of the nature of the elements which enter into the composition of a substance. Thus, determining that hydrogen, sulphur, and oxygen are contained in sulphuric acid. *Quantitative analysis* is the determination of the amount as well as the nature of the elements which enter into the composition of a substance. Thus, determining that sulphuric acid contains two parts by weight of hydrogen, 32 of sulphur, and 64 of oxygen.

6. *Mineral waters* are waters which are of therapeutic value by reason of the nature or quantity of dissolved solids which they contain, or which have a temperature greater than 68° F. *Examples:* Hunyádi, Saratoga Springs, and Vichy.

Acids are compounds of an electronegative element or radical with hydrogen, part or all of which hydrogen they can part with in exchange for an electropositive element, without formation of a base. *Examples:* Sulphuric acid, H_2SO_4; nitric acid, HNO_3.

Bases are ternary compounds capable of entering into double decomposition with an acid to produce a salt and water. *Examples:* Potassium hydroxide, KOH; calcium hydroxide, $Ca(OH)_2$.

Salts are substances formed by the substitution of an electropositive element for part or all of the replaceable hydrogen of an acid. *Examples:* Sodium nitrate, $NaNO_3$; Monopotassic sulphate, $KHSO_4$.

8. A *poison* is any substance which, being in solution in, or acting chemically upon, the blood, may cause death or serious bodily harm. Thus arsenic, after being absorbed, is a poison. But corrosives, such as sulphuric acid, act locally; so, if a man fell into a vat of sulphuric acid, though he might die from it, it would not be correct to say he was poisoned.

9. *In death by drowning:* The surface is pallid, the face appears tranquil, the eyes and mouth being partly open. The skin often has the appearance known as goose-skin, and, if the body has lain upward of twelve hours in the water, that of the hands and the feet is sodden by inhibition. The most important external sign is the presence on the mouth and nostrils of a fine froth (possibly blood stained), composed of air, mucus, and the medium in which drowning took place; if the body remains three or four days in water, the froth disappears. Exceptionally, fragments of weeds or other small objects may be found tightly grasped in the hands. On opening the thorax the lungs, gray in color, with reddish staining, are seen to be very voluminous, a condition known as ballooning, partly due to infiltration of the lung tissue with some of the medium in which drowning took place, and partly to true edema. The lung substance is inelastic and pits on pressure. On section, fluid and froth resembling that found on the lips exude from the divided air passages. Minute subpleural hemorrhages are not infrequently present, and the pleural cavities may contain fluid. The stomach often contains water or other liquid which was involuntarily swallowed during attempts at respiration. Occasionally some of this fluid is forced by vital action into the intestines. With one exception, the remaining appearances are those met with after death from asphyxia. The exception is constituted by the blood, which is not only dark colored and fluid, as is usual after death from asphyxia, but is also diluted by the imbibition of water from the stomach and lungs.—(Quain's *Dictionary of Medicine.*)

10. The *medical evidence of rape* is based on: (1) Marks of violence about the woman's genital organs; (2) wounds, bruises, or other marks of injury on the woman or on the accused; (3) blood stains and seminal stains on the person or clothing of either party; and (4) the presence of any venereal disease on either party.

BACTERIOLOGY AND HYGIENE.

1. *Bacteria are classified* as: (1) *Cocci*, which are round or oval, and may appear singly, in pairs, in chains, or in groups; example—streptococcus of erysipelas. (2) *Bacilli*, which are rod shaped, with the longer sides parallel and the short ends either straight, rounded, or concave; example—bacillus of tetanus. (3) *Spirilla*, which are spiral; example—spirillum of relapsing fever.

2. *Bacteria found in soil: Bacillus tetani, Bacillus, edematis, Bacillus aërogenes capsulatus, Bacillus proteus, Bacillus subtilis*, anthrax bacillus, typhoid bacillus, *Bacillus coli communis, Bacillus proteus.*

Bacteria found in water: Typhoid bacillus, cholera spirillum, streptococci, *Bacillus proteus, Bacillus aërogenes capsulatus, Bacillus subtilis, Bacillus fluorescens liquefaciens, Bacillus coli communis.*

Bacteria found in milk: Bacillus of lactic acid, *Streptococcus lacticus, Bacillus aërogenes*, bacillus of anthrax and of malignant edema; bacillus of typhoid, of tuberculosis, of cholera, and of diphtheria.

Bacteria found in air: Bacillus subtilis, tubercle bacillus, pyogenic cocci, various forms of micrococci and sarcinæ.

3. *Toxins* are the poisonous products of pathogenic bacteria or of ptomaines or leucomains. *Antitoxins* are substances formed in the body, of a protective character, and

capable of rendering inert the poisonous products of bacteria. *Examples:* Antitoxins of diphtheria, plague, streptococcus, tetanus, tuberculosis, and typhoid.

4. *Phagocytosis* is the faculty of certain cells (notably the mononuclear and polynuclear leucocytes) to take up and destroy bacteria.

5. See Rose and Carless' "Surgery" (1911), pages 205 and 207; or Da Costa's "Surgery" (1908), pages 25 and 50.

6. To *obtain a culture:* A sterile swab is rubbed over any visible membrane on the tonsils or throat, and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it, and placed on a clean cover slip, and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appear as short, thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts.

7. *Pure water* is colorless, odorless, cool, without disagreeable or salt or sweetish taste, and is free from bacteria, poisons, foreign bodies, etc.

Characteristics of a good drinking water. (1) It should be clear and limpid. Cloudy and muddy waters should be avoided. (2) It should be colorless. A greenish or yellowish color is usually due to vegetable or animal matter in solution or to organisms. (3) It should be odorless; especially free from sulphuretted hydrogen or putrefactive animal matter. (4) It should not be too cold, but should have a temperature of from 46° F. to 60° F. (5) It should have an agreeable taste; neither flat, salty, nor sweetish. A certain amount of hardness and dissolved gases give a sparkling taste. It should contain from 25 to 50 c.c. of gases per liter, of which 8 to 10 per cent. is carbon dioxide and the rest oxygen and nitrogen. (6) It should be as free as possible from dissolved organic matter, especially of animal origin. (7) It should not contain too great an amount of hardness. A certain quantity of saline matter is necessary, however, to give it a good taste. It should not contain over three or four parts of chlorine in 100,000 parts of water.—(From Bartley's *Chemistry.*)

Contaminated water is purified by: Distillation, boiling, filtration, precipitation, and various chemical processes.

8. "It is a common belief that if the well is located in higher ground than the cesspool there can be no danger of pollution of the water. This, however, is a most fallacious proposition, for it is not so much the location of the outlet of the well that determines the possibility of pollution as the relative position of the cesspool and the point where the water enters the well. . . . Again, the geological formation may be such that a cesspool on higher ground than the nearby well will have no influence on the purity of the water. Thus a ledge of rock may crop up between them, and divert the flow of polluting matters away from the well." (Harrington's *Hygiene.*)

9. Hygienic precautions to be taken in treating a case of tuberculosis: "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine.*)

10. Air of schoolrooms may be contaminated by the respiration of scholars and teachers; products of combustion from the heating apparatus, also from the lighting apparatus, dust, epithelial cells, and disease germs.

Modern methods of heating and lighting should be adopted; ample ventilation should be insisted on; children who are not in good health should be excluded, the schoolroom should not be used for any purpose after school hours.

PRACTICE OF MEDICINE AND PEDIATRICS.

1. See French's "Practice of Medicine" (1910), pages 1153, 1150, and 1155; or Osler's "Practice of Medicine" (1909), pages 1052 and 1047.

2. See French's "Practice of Medicine" (1910), pages 662 and 668; or Osler's "Practice of Medicine" (1909), pages 814 and 816.

3. See French's "Practice of Medicine" (1910), page 882; or Osler's "Practice of Medicine" (1909), page 791.

4. See French's "Practice of Medicine" (1910), pages 151, 150, 171, and 174; or Osler's "Practice of Medicine" (1909), pages 165, 172, 175, and 180.

5. See French's "Practice of Medicine" (1910), pages 65, 193, 74, and 109; or Osler's "Practice of Medicine" (1909), pages 57, 93, 70, and 99.

6. See French's "Practice of Medicine" (1910), pages 713 and 715; or Osler's "Practice of Medicine" (1909), pages 651 and 653.

7. See French's "Practice of Medicine" (1910), pages 801 and 800; or Osler's "Practice of Medicine" (1909), pages 507, 500, and 504.

8. For an infant of three months, Winters advises the following:

Take the upper eleven ounces from a quart of milk, 16 hours after milking.

Milk-sugar, about 7½ teaspoonfuls.

Lime-water, 4 ounces.

Filtered water, enough to make one quart.

Quantity at each feeding, 3 ounces.

Eight feedings, at 6, 8:30, 11 A. M.; 1:30, 4, 6:30, 9 and 12 P.M.

9. Causes of infantile convulsions are: "Overeating, especially of indigestible food; rachitis, debility from exhausting diarrheal diseases; high fever, especially at the onset of the acute specific infections; very seldom dentition, phimosis, and acute middle-ear inflammation; injuries to the brain at birth, infantile hemiplegia, meningitis, and tumor of the brain; rarely of spinal cord disease.—(From Butler's *Diagnostics of Internal Medicine.*)

10. See French's "Practice of Medicine" (1910), pages 798 and 799; or Osler's "Practice of Medicine" (1909), page 504.

OBSTETRICS AND GYNECOLOGY.

1. See Jellett's "Midwifery" (1910), pages 93 to 97; or Hirst's "Obstetrics" (1909), pages 120, etc.

2. PELVIS. *Bones:* Right and left innominate bones (each consisting of ilium, ischium, and pubis), sacrum, and coccyx. *Straits:* Superior and inferior. *Divisions:* True and false.

3. See Jellett's "Midwifery" (1910), pages 10 and 7; or Hirst's "Obstetrics" (1909), pages 18 and 22.

4. See Jellett's "Midwifery" (1910), pages 114 and 308.

5. SIGNS OF PREGNANCY: "The *positive signs* cannot usually be detected until after the fourth month, and are three in number: (1) hearing and counting the fetal heart-beat; (2) perception of the active and passive movements of the fetus; and (3) the ability to map out its outlines. The *probable signs* can be appreciated at a much earlier period, and are: (1) changes in the shape and consistency of the body of the uterus; (2) changes in the cervix; (3) the detection of intermittent uterine contractions; and (4) increase in the size of the abdomen and uterus. The *presumptive evidences*, with a few exceptions, are subjective, and may be experienced at varying periods. They are: (1) cessation of the menses; (2) changes in the breasts; (3) morning sickness; (4) quickening; (5) Chadwick's sign; (6) disturbances in urination; (7) abnormalities in pigmentation; (8) abnormal cravings; and (9) mental disturbances."—(Williams.)

6. See Jellett's "Midwifery" (1910), page 584; or Hirst's "Obstetrics" (1909), page 249.

7. See Jellett's "Midwifery" (1910), page 489; or Hirst's "Obstetrics" (1909), pages 148 to 153.

8. *Abortion* is delivery of the product of conception before the twelfth week.

Miscarriage is delivery of the product of conception between the twelfth and twenty-eighth weeks.

Premature labor is delivery of the fetus between the twenty-eighth week and full term.

9. See Jellett's "Midwifery" (1910), page 353; or Hirst's "Obstetrics" (1909), page 343.

10. See Jellett's "Midwifery" (1910), page 463; or Hirst's "Obstetrics" (1909), pages 365 and 376.

SURGERY.

1. *Methods of controlling hemorrhage* Ligation, suture, torsion, pressure, elevation, styptics, cautery, forced flexion, heat, cold, ergot, suprarenal extract.

2. *Tincture of iodine is used in modern surgery:* (1) To cleanse the skin; (2) as an application to infected wounds; (3) to irrigate sinuses.

3. See Rose and Carless' "Surgery" (1911), pages 490 and 497; or Da Costa's "Surgery" (1908), pages 487 and 488.

4. See Rose and Carless' "Surgery" (1911), page 398; or Da Costa's "Surgery" (1908), page 1058.

5. See Rose and Carless' "Surgery" (1911), page 201; or Da Costa's "Surgery" (1908), page 242.

6. See Rose and Carless' "Surgery" (1911), pages 1074 and 1077; or Da Costa's "Surgery" (1908), pages 891 and 894.

7. See Rose and Carless' "Surgery" (1911), page 518; or Da Costa's "Surgery" (1908), page 506.

8. See Rose and Carless' "Surgery" (1911), pages 121 and 123; or Da Costa's "Surgery" (1908), page 201.

9. See Rose and Carless' "Surgery" (1911), page 1245; or Da Costa's "Surgery" (1908), pages 138 and 143.

10. See Rose and Carless' "Surgery" (1911), pages 1117, 1119, and 1121; or Da Costa's "Surgery" (1908), pages 904 and 905.

SPECIAL PRACTICE.

1. See French's "Practice of Medicine" (1910), pages 1119 and 1001; or Osler's "Practice of Medicine" (1909), page 911.

2.

EPILEPSY.	HYSTERIA.
1. No apparent cause.	1. Cause, emotional.
2. Sudden and rapid onset.	2. Onset gradual, usually after some mental excitement.
3. Aura generally present.	3. Globus hystericus or palpitation.
4. Consciousness lost.	4. Consciousness generally preserved.
5. Pupils general dilated.	5. Pupils normal.
6. Tongue often bitten.	6. Tongue never bitten.
7. Patient very liable to hurt himself.	7. Patient not liable to hurt himself; may injure others.
8. May be involuntary bladder and bowel discharges.	8. Never.
9. Of short duration.	9. Duration longer.

3. *Otorrhea may be caused by:* Otitis media, with or without complications; abscess or polypus in the external meatus. *Dangers:* Thickening of tympanum, destruction of ossicles, caries of mastoid, facial paralysis, inflammation or abscess of brain or meninges, pyemia, infective thrombosis of lateral sinus or jugular vein.

4. Scarlet fever is the disease in which the ear is most commonly involved. The tympanum is generally first attacked.

5. *Conjunctival diseases due to microorganisms* Conjunctivitis, ophthalmia neonatorum, pink eye, gonorrheal ophthalmia, diphtheritic conjunctivitis, trachoma.

6. IRITIS. *Four causes:* Rheumatism, syphilis, gout, and gonorrhea. *Subjective symptoms:* Pain, photophobia, lacrymation, interference with vision, and malaise. *Objective symptoms.* The iris is swollen, dull, lacks luster, changes color, is congested; the pupil is contracted, sluggish in action and irregular; circumcorneal injection is present; the contents of the aqueous chamber are turbid, and may show pus, or fibrin, or blood.

7. In *nephritis* the effusion of serum begins in the face and extends downward; or in the upper half of the body. In *cirrhosis of the liver*, in the lower half of the body. In *cardiac diseases*, at the feet and extends upward.

8. In *chlorosis* a blood examination shows marked diminution of hemoglobin, slight diminution of red cells, poikilocytosis, and in severe cases nucleated red cells. The diagnosis is certain. In *appendicitis* leucocytosis is fairly constant, except in the mildest and most severe cases. The blood examination will differentiate this condition from typhoid. It is a valuable help in diagnosis, but there is nothing absolutely certain about it. In *trichinosis* there is a leucocytosis with a pronounced eosinophilia. It is of great diagnostic value.

9. See French's "Practice of Medicine" (1910), page 663; or Osler's "Practice of Medicine" (1909), page 598.

10. NASAL POLYPI. These are of two different origins (1) Inflammatory, and (2) neoplastic.

1. *Mucous polypi* are merely edematous granulations hanging from the surface of a diseased ethmoid bone, which is affected by rarefying ostitis or caries. They occur in young adults, and cause nasal obstruction, often bilateral. Grow from the middle and superior turbinate bones. They frequently undergo cystic degeneration from the development of cysts in the glands of the mucous membrane covering them. After local removal they recur within a few months.

Treatment: (*a*) Removal by wire snare under cocaine. (*b*) Usually a thorough erasion of the lateral mass of the ethmoid or the opening of a suppurating sinus is required, so as to remove the diseased bone.

2. *Fibrous and sarcomatous polypi.*—Consist in all gradations between fibromata and sarcomata, usually beginning as the former and ending as the latter. Occur in children and adolescents most commonly. Grow from the base of the skull and occupy the nasopharynx. Cause nasal obstruction with sanious discharge. *Pressure signs* may be: (1) Pushing down the velum palati and causing asphyxia; (2) expanding the nasal cavities and producing a widening of the nasal bridge; (3) pressing the eyeballs outward; (4) extending into the base of the brain. *When they are malignant*, secondary growth may occur in the lymph glands of the neck. In these cases the primary growth is probably a lymphosarcoma of the pharyngeal tonsils.

Treatment is possible only in the early stages. In suitable cases, when the growth has not progressed far: (1) Removal by a snare through the anterior nares; (2) removal through the mouth after splitting the soft palate, (3) removal from the face after turning up the soft parts and enlarging the anterior nares by temporary displacement of the maxilla.—(Groves' *Synopsis of Surgery.*)

ADVANCED REQUIREMENTS OF PRELIMINARY EDUCATION.

(From the Bulletin of the Illinois State Board of Health.)

A medical student desiring to enter into practice in a certain state would do well to see if his chosen college is fully recognized in that state. The several states named below have enacted requirements of preliminary training in excess of those generally called for. In these a high school education is no longer accepted as a qualification for admission to a medical school. Instead—and in addition—there is demanded evidence of one or more years' attendance in a college or university of arts and sciences. In Utah the advance requirements are specifically provided for by law. In the other States mentioned they have been prescribed by the rules of the State Medical Board.

The States exacting one or more years of college work are as follows:

State.	Years.	In Force.	Affecting Graduates of
Colorado	2	1911	1914
Connecticut	1	1910	1914
Indiana	1	1910	1913
Indiana	2	1911	1914
Iowa	2	1911	1915
Kansas	1	1910	1914
Minnesota	2	1908	1912
North Dakota	2	1908	1912
South Dakota	2	1907	1911
Utah	1	1913	1917

More detailed information concerning the requirements in the above States may be obtained from the respective secretaries, as follows:

Colorado: Dr. David A. Strickler, Secretary State Board of Medical Examiners, Denver.

Connecticut: Dr. Charles A. Tuttle, Secretary Medical Examining Board, representing Connecticut Medical Society, New Haven.

Indiana: W. T. Gott, M.D., Secretary State Board of Medical Registration and Examination, Indianapolis.

Iowa: Dr. Guilford H. Sumner, Secretary State Board of Medical Examiners, Des Moines.

Kansas: Dr. Henry A. Dykes, Secretary State Board of Medical Registration and Examination, Lebanon.

Minnesota: Dr. W. S. Fullerton, Secretary State Board of Medical Examiners, St. Paul.

North Dakota: Dr. G. M. Williamson, Secretary North Dakota State Board of Medical Examiners, Grand Forks.

South Dakota: Dr. L. G. Hill, Secretary State Board of Medical Examiners, Watertown.

Utah: Dr. George E. Harding, Secretary State Board of Medical Examiners, Salt Lake City.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W H Sanders, Montgomery	Montgomery	July 9
Arizona*	Ariel Martin, Phoenix	Phoenix	April 1
Arkansas	F T Murphy, Brinkley	Little Rock	May 14
California*	Chas L Tisdale, 929 Butler Bldg, San Francisco	San Francisco	April 2
Colorado	David A Strickler, Empire Building, Denver	Denver	April —
Connecticut*	Chas A Tuttle, New Haven	New Haven	Mar 12
Delaware	J H Wilson, Dover	Dover	June 18

*No reciprocity recognized by these States

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State

Vermont.—The refraction test is no longer required of applicants for a license to practise medicine.

Louisiana.—At the October examination there were thirty-six candidates; of this number twenty were successful.

Ohio has reciprocity with the following States upon certificates issued after an examination only: New York, New Jersey, Illinois, and Texas. With the following upon certificates by diploma as well as by examination: Arkansas, Colorado, District of Columbia, Indiana, Iowa, Kansas, Louisiana, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Vermont, West Virginia, Wisconsin, Wyoming, Kentucky.

Influence of Rest and Movement on the Elimination of Ammonia in the Urine.—Giuseppe Moscati divides the nitrogen in the urine into weak and non-weak. This division covers our ignorance of the composition of many substances which are midway between albumin and urea. He has made tests in man and animals of the elimination of ammonia during rest and after exercise. These results are tabulated and the conclusions are given. The ammonia eliminated in man varies with repose or labor; it increases during rest, and diminishes or disappears on exercise, whether the patient is on ordinary or milk diet. On a flesh diet the amount of ammonia, whether during rest or exercise, varies little. On a vegetable diet the inverse is true: there is an increase of ammonia during exercise. The probable explanation of these facts is that there is a fixation of a part of the acids of metabolism by the alkalies which result from the disintegration of the tissues, thus leaving ammonia free to be synthesized into urea. In dogs with exercise caused by small doses of strychnia no results were obtained on account of the interference of the drug with the normal metabolism. In horses exercise determined a disappearance of ammonia from the urine, the ammonia being elevated and synthesized into urea.—*Giornale Internazionale delle Scienze Mediche.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended January 20, 1912.

	Cases	Deaths
Tuberculosis Pulmonalis	457	171
Diphtheria	247	31
Measles	616	6
Scarlet Fever	252	5
Smallpox	1	—
Varicella	253	—
Typhoid Fever	87	9
Whooping Cough	29	2
Cerebrospinal Meningitis	2	4
Malarial Fever	—	—
Totals	1,914	228

Treatment of Torticollis.—Desfosses describes torticollis as a shortening of one sternocleidomastoid muscle so as to turn the head to one side, while the spine undergoes a scoliosis with the convexity toward the healthy side. Formerly this trouble was supposed to be due to the neglect of the accoucheur, but at the present day it is believed that such an accident can happen only in a muscle already pathological, and Couvelaire demonstrated in such cases post-mortem that there was degeneration of some of the muscle fibres. For the cure of the condition there must be a section of the muscle, either subcutaneously or after an incision; this is followed by a plaster dressing to maintain the head in a position of over-correction, which dressing is worn for a week; then an apparatus for the same purpose should be worn for a month. At the end of this time active and passive movements are begun to preserve the length of the muscle and develop its strength. The result is generally perfect.—*La Presse Médicale.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended January 10, 1912.

RÉSUMÉ OF THE IMPORTANCE AND PREVALENCE OF THE OCCUPATIONAL DISEASES.*

By W. GILMAN THOMPSON, M.D.,

NEW YORK.

THE occupational or industrial diseases are beginning to attract in this country the systematic study which has been bestowed upon them for some years past in Germany, France, and England, where it has been shown that an increasingly large variety of diseases are directly attributable to occupational hazards of many kinds.

The study of the conditions under which these diseases develop invites attention alike from the humanitarian, scientific, and purely economic points of view.

The multiplicity of manufactures, the crowding together of large numbers of working people in ill-ventilated factories, the strain of tending certain kinds of machinery, the danger of handling many varieties of metals and chemicals, the stress of hurry and competition, the common ignorance and carelessness regarding dangers grown familiar through constant association, as well as the lack of authoritative supervision of hazardous occupations, are all contributing factors to the group of occupational diseases. While none of these diseases involve new fundamental principles of pathology, yet they are new in etiology and prophylaxis, and their symptoms, in sequence and rapidity of development, as well as in grouping, often constitute unique and distinguishing features. Thus it has come to pass that in our complex civilization the evolution of new machinery and apparatus, of new varieties of food and drink, of new occupations and habits of life—in a word, of our whole environment—has been accompanied by the employment of new poisons in the mechanical art, new irritants for inhalation, new uses for the muscles, new strains for the nerves, and new stress of the mind. Many of these factors operate most insidiously, others more acutely; but, sooner or later, they tend to injure the structures of the body or alter its activities in a manner to produce what fairly may be regarded as new diseases or disorders, and consequently to affect longevity and mortality in very striking degree. Thus, for example, there are 150 trades in which exposure to lead in various forms may occasion serious and sometimes fatal plumbism. In this city not long ago three deaths from lead poisoning occurred among the men employed in a single lead smelting establishment, and I have collected the histories of 267 cases of serious lead poisoning treated within a few years in only three of our medical institutions. Dr. Alice Hamilton, working on a special commission in Illinois to investigate the prevalence of lead poisoning, found cases of plumbism in 33 of 56 establishments where lead was used in processes of manufacture, with a yearly average of 665 cases. In England, in the white lead works in the neighborhood of Newcastle, compulsory medical inspection has so far reduced the cases of lead poisoning that in 1910 the ratio was 1 case in 264 employees, whereas in Illinois, without legalized inspection and control, Dr. Hamilton found the ratio 1 case in 7 employees.

There are twenty-seven trades in which arsenic constitutes a similar hazard.

Dr. Frederick L. Keays of the staff of the Cornell University Medical Clinic, while serving as physician to the Pennsylvania Railroad Tubes, published a report concerning 3,692 instances of caisson disease occurring among the 10,000 workmen employed, and including 20 deaths. Mr. John B. Andrews of the American Association for Labor Legislation, in his recent investigation of phosphorus poisoning among those employed in the manufacture of matches in this country, found records of 40 cases of necrosis of the jaw in a single factory. "Of this number 15 cases resulted in the loss of one or both jaws, and several cases resulted in death." In another small factory there were records of 21 cases, 6 of which developed in a single year.

There are many trades in which the hazard to the unprotected workmen is equally great, although the facts are less widely known. Thus workmen who inhale the chromic acid used in the production of chrome pigments may acquire deep ulceration of the mouth, and I have seen necrosis of the upper jaw which destroyed completely the floor of the nasal cavities. Those employed in the pressing and glossing of silk hats are subject to serious mercury poisoning. A salt of mercury used to produce the gloss is pressed in with hot irons, which volatilize the mercury. Workers in pottery and porcelain are subjected both to lead poisoning from the glazing materials andto pneumoconiosis and chronic bronchitis from inhalation of particles of flint, silica and other substances. In many of the occupations in which the inhalation of dust constitutes the chief hazard, the victims not only suffer from the effects of constant irritation of the bronchi and lungs, but the lesions thus produced render them especially liable to the subsequent acquisition of tuberculosis. In Lancashire, for example, in some years the deaths from tuberculosis among cotton spinners and weavers have risen as high as 20 per cent. of the total deaths from that disease.

Such are a few examples only of the prevalence of the industrial diseases, which serve to illustrate the importance of a subject which is beginning to

* Introduction to a discussion on Occupational Diseases at the N. Y. Academy of Medicine, Committee on Public Health, etc., meeting, Jan. 4, 1912.

excite widespread attention and call for preventive measures, legislative and otherwise.

June, 1910, was signalized by the meeting in Chicago of the first National Conference on Industrial Diseases, and, in a memorial sent to President Taft by this conference, it was stated that there occur annually in the United States 13,400,000 cases of sickness among artisans and craftsmen, many of which are attributable directly to special occupational hazards, involving a total annual economic loss of nearly three-fourths of a billion dollars. It is high time, therefore, that physicians bestir themselves to look carefully into the problems involved and aid in gathering accurate data in order clearly to differentiate the influence of occupational environment and hazard in special lines of work, for on such data only may be based proper legislative action.

The United States Census Bureau has lately issued a partial classification including 101 diseases due to hazardous occupations, under which death returns or other statistics should be grouped. The States of Illinois and New York have established commissions to investigate the problems of the occupational diseases, particularly in relation to providing suitable factory legislation.

Thus far six States, California, Connecticut, Illinois, Michigan, New York, and Wisconsin, have passed laws requiring physicians to report certain cases of occupational disease whenever found. These diseases are derived from four metals, lead, mercury, arsenic, and phosphorus; one germ, the anthrax bacillus, and the caisson disease. The reports must be made either to the State Board of Health, as in four States, or to the State Labor Bureau, as in two States, including New York. Penalties varying from $10 to $100 may be imposed for failure to report. This is a scant list, in some respects not well selected, but it constitutes a beginning and should serve to interest the cooperation of physicians in gathering important facts which heretofore have never been tabulated in this country. Legislation aimed at the mitigation of the evils of unhygienic mills, factories, and hazardous trades is doubtless desirable in many instances, but it is a grave mistake to enact it too hastily before the existing evils are better understood, both as to their nature and extent. In this work the active assistance of physicians is absolutely essential, especially of those living in manufacturing towns whose dispensary or hospital opportunities bring them in direct contact with many illustrations of the occupational diseases.

In order to render such statistics of value, it is most desirable to establish agreement upon a definite nomenclature, both of the hazardous trades, the noxious substances encountered, and the diseases incident thereto. Thus far the literature of the occupational diseases is so meager, consisting, as it does, of less than a half dozen books in English and a few scattered journal articles and insurance reports, that physicians generally are unfamiliar with very many of the occupation hazards, as a glance at the statistical records of hospital cases easily demonstrates. It is to be hoped that the Census Bureau will shortly take this matter into consideration, and in New York State the Labor Bureau is about to issue to physicians a nomenclature and classification for information and guidance in returning uniform statistics.

In many instances better ultimate results may doubtless be obtained through a campaign of education than by means of legislation. Some of the large corporations have already found the enormous economic advantage in protecting workmen from injury by accidents, instance the admirable example of the Illinois Steel Corporation, which, without legislative compulsion, has found it economical to expend over $1,000,000 a year in devices for protection of its workmen and in issuing printed circulars of information to instruct them in the avoiding of accidents. That such results would accrue from similar appreciation of the economic advantage of avoiding disease hazards there can be no question.

Another important phase of the subject of occupational diseases concerns employers' liability, which in several foreign countries is now made to cover industrial diseases as well as accidents. In England, for example, in a single year damages were awarded in over 2,000 cases of industrial disease arising from ten of the hazardous substances enumerated by Parliamentary act.

In the larger cities of Europe fourteen museums have already been established to illustrate, by means of models, charts, diagrams, etc., the hazardous occupations, as well as the means of prophylaxis. In this country the first museum of the kind has been established in New York, and it is intended to exhibit the occupational hazards of disease, such as the various dusts, metallic salts, etc., as well as safety appliances for ventilation of factories, and other forms of protection.

To Milan belongs the credit of establishing in 1910 the first hospital for the treatment and study solely of occupational diseases. It is an admirably appointed institution, containing, besides 150 beds for patients, extensive chemical, physical, and pathological laboratories and an amphitheater for instruction.

The American Medical Association, the New York State Medical Association, the International Association for Labor Legislation, the American Economic Association, and the New York Academy of Political Science are among the numerous organizations which recently have shown encouraging interest in the problems of the occupational diseases through the appointment of special committees to investigate them.

This brief general introductory outline may serve to emphasize the many-sided interests which the study of the diseases of occupation presents, and in which European countries are already considerably in advance of our own. To the others who are to participate in this discussion must be left the more detailed presentation of the subject.

34 East Thirty-first Street.

STATE CONTROL OF OCCUPATIONAL DISEASES.*

By LEONARD W. HATCH, Ph.D.

ALBANY, N. Y.

CHIEF STATISTICIAN, NEW YORK STATE DEPARTMENT OF LABOR.

Why should the physicians of New York be required to report occupational diseases to the State government? More particularly, why should they report such diseases to the State Department of Labor, as required by Chapter 258 of the Laws of 1911, which took effect on the first of last September? It is to endeavor to answer these questions, briefly, that

*Read at a meeting of the New York Academy of Medicine, January 4, 1912.

I have been glad to avail myself of your committee's invitation to address this meeting.

At the very outset, it is suggested that, while my position is that of a department official to whom it falls to conduct administrative work connected with seeing that the required reports are sent in, while you, or so many of you as belong to the medical profession, are in the position of those required to send in those reports, it will greatly tend to clarify our view of the whole matter if it be considered almost entirely from the social point of view instead of from the personal point of view of either party directly concerned. Certainly it is only from that point of view that a correct notion of it can be secured.

Considered thus broadly, the matter is essentially one of the public health. Physicians have long been familiar with governmental regulations, local or State, touching various phases of public health, in connection with which they are called upon to observe certain requirements, mainly in the way of furnishing information to public authorities. A familiar example of these is the quarantine regulations in connection with contagious diseases. The direct and serious menace to the public generally from a case of contagious disease left free to propagate itself in the community through ignorance or carelessness makes very obvious the wisdom and advantage to the public as a whole of such regulations and the required duties of physicians in connection therewith. Another example, more closely analogous to the case in hand, is the compulsory registration of deaths, where perhaps, to many physicians, the practical bearing of the regulation upon the general public health may not be so clear as in the case of quarantine regulations. In the one case a physician is required to report to local authorities the existence of what his technical knowledge tells him is of itself a direct menace to the neighboring community. In the other he is required to report to the public authorities what, indeed, his technical knowledge alone can furnish (that is the cause of death), but what neither immediately nor directly, in the vast majority of cases, menaces the health of the surrounding community. But the public service rendered by the physician in the latter case may be just as practical and important to the public health as in the former, though much less immediate and direct in its effects. Here is a concrete example, which happens to be within the writer's knowledge. Several years ago the city of Albany had a very high death rate from typhoid fever. This general fact, which could only be established by public registration of deaths, called attention to the question of the purity of the water supplied to the citizens, which finally led to the installation of a system of filtration of the water, which was taken from the Hudson River, with the result that the typhoid rate was rapidly and steadily reduced to one not above the normal in recent years. Here, it will be seen, is a very practical result, quite as important for the public health as preventing the spread of a contagious disease, directly traceable to the information afforded by physicians' reports of deaths. In other words, knowledge of the frequency and incidence of a given disease as a cause of death, which could only be had by general registration, proved to be the primary means to the prevention of that disease.

Now, the above familiar examples of requirements laid upon physicians for the sake of the public health in the case of contagious diseases and registration of deaths may serve very well for more than mere illustration; because, as a matter of fact, the reason for the reporting of occupational diseases to the State Department of Labor is precisely the same in principle as that for the reporting by physicians to local boards of health of deaths and contagious diseases, and a comparison of the two will, perhaps, best serve to make clear the reasons for reporting of occupational diseases.

Note, first of all, the points of similarity. In both cases the physician is required to furnish information which he alone can supply, since only the physician can accurately identify diseases. In both cases this information is to be furnished to a public authority for the purpose of enabling that authority either to enforce immediately preventive regulations or to bring together comprehensive information as to the causes of disease or death, to the end that the need of preventive measures, and the kind of such measures required, may be understood. The differences lie only in the class of information required and the public authority to whom it is to be furnished, the latter, in the case of occupational diseases, being largely determined by the former.

You have already heard of the importance and prevalence of occupational diseases. The thing to be emphasized in the present connection is that these diseases, except in the case of tuberculosis due to occupational causes, are a matter not of the health of the whole community, as in the case of the reporting of contagious diseases, or general registration of deaths, but only of a certain portion of it, although the most numerous one, namely, the wage-earners of our industrial population. It is for this reason that the term industrial disease has come into common use as practically synonymous with the broader term, occupational disease. It is certain of these industrial diseases which constitute the new class of information required of physicians under the new law. (Why the selection of certain ones only is made will be explained hereafter).

Now, it happens that the health of industrial workers has long been a subject of legislation in all civilized countries, because it was long ago discovered that without such laws the short-sightedness or rapacity of employers, and ignorance or pressure of the struggle for existence in the case of employees, would inevitably lead to large numbers of wage-earners being employed under conditions highly deleterious to health. Accordingly, factory laws, and more recently laws applying to other forms of industry, have been enacted to prevent over-long hours for women and children, to prevent overcrowding, to require proper ventilation, toilet facilities, cleanliness, etc., all these being nothing more or less than health laws. Furthermore, such matters of industry being chiefly within the province of State legislation in this country, the States have very generally established labor bureaus or departments for the enforcement of such laws or investigation of conditions with a view to further legislation. In other words, industrial hygiene has long been assigned to special State agencies like the New York State Department of Labor for investigation, or administration of laws designed to promote the same. And this is the reason why the State Department of Labor is the perfectly natural public authority to which the new law makes industrial diseases reportable. It is the established State agency dealing with matters of industrial hygiene, just as local boards of health are the established agencies dealing with matters relating to the general health of the community.

If the foregoing makes it clear that this new law does not inaugurate something that is revolutionary in principle, but only applies to a new or special field familiar and established practise in other fields, it may be helpful to note more fully the broader significance for its own field of industrial hygiene of this new step.

It was noted above that laws to conserve the health of industrial workers have long been on the statute books. But almost without exception in this country up to the present time, such laws have been confined to very general requirements of a few elementary conditions. Thus in New York State the present factory law contains only such general requirements with reference to lighting, ventilation and overcrowding, time for meals, cleanliness of workplaces, plumbing and drainage, and toilet facilities, and some of these have been found in actual practice to be inadequate. Such requirements deal only with matters of common knowledge; with certain simple essentials of sanitation not peculiar to factories or industrial life, but recognized as essential everywhere. In other words, thus far labor laws have to a large extent attempted little more than to see that factories and industrial establishments shall not fall below the elementary standards of sanitation recognized as necessary everywhere. Very little has been done toward the establishment of special regulations for the elimination of those special dangers connected with the use of harmful substances or processes, which are the prolific source of disease to workers exposed to them, as you have heard from the preceding speakers. And it is becoming more and more evident that the great line of progress for the future toward industrial hygiene lies chiefly in this field.

Now, if this progress is to be made in scientific fashion, and unless it be scientific, it will fail of the highest effectiveness, it must be based, first of all, on thorough investigation and knowledge of the facts. Some valuable studies in this field have already been made in this country, and in New York State three years ago an important step in this direction was taken in the appointment in the Bureau of Factory Inspection of a medical inspector of factories, such appointment being unique in the history of such bureaus at that time in this country. But if the problem is to be comprehensively studied and treated, the necessary starting point would seem clearly to be adequate knowledge of the frequency, and location in industries and establishments, of these occupational diseases. To borrow a medical term, a comprehensive diagnosis of this social ill must be the first step. For this the indispensable means is the registration of such diseases, and, as already pointed out, it is at this point, just as in the case of contagious diseases or registration of deaths, that the public authorities must call upon the only source of information, the medical profession. For the field of industrial hygiene, therefore, this new reporting law represents a most important step forward toward a broad and scientific treatment of the special dangers menacing wage-earners, supplementing the older and more primitive requirements of labor laws. These latter could be formulated on the basis of the common knowledge of men concerning such matters; regulations for the control of occupational diseases require as a basis special knowledge. It is in large degree, therefore, for the necessary basis of a vastly important forward movement in the interests of the health of the industrial population that the law for the reporting of industrial diseases calls upon physicians.

While the road toward control of occupational diseases above outlined must commend itself as reasonable and scientific, it is important to observe that it is far from one wholly untried when foreign experience is noted. No country has a higher reputation for efficient and progressive efforts by direct State inspection and regulation to promote industrial hygiene than Great Britain, and it is safe to say that a very important element contributing to this success has been the large measure in which the British authorities have enlisted the cooperation of the medical profession in their work. Particularly in this very field of diseases due to occupation is this true, and for years the British factory law has required registration of such diseases precisely as provided for in the New York law. In fact, the New York law is copied verbatim from the English act, so that the American Association for Labor Legislation, which was the original proposer of the New York law as well as similar laws passed this year in several other States, did no more than propose the adaptation to the American problem of industrial diseases of a tried and proven method in advanced practice abroad.

In the short time here available it has been both necessary and desirable to consider principally the more general aspects of reporting by physicians as a factor in State control of occupational diseases, so that any full discussion of the New York law in detail is out of the question. But there are two matters connected with details of the law, to which it is appropriate to call attention here.

The law lays on physicians the specific duty of reporting only certain diseases, namely, poisoning by lead, phosphorus, arsenic, or mercury, anthrax and caisson disease. As has been made apparent by the preceding paper, this is but a very small number out of a very large list of diseases to which workers are liable from the nature of their work. The selection made in the law must be regarded as more or less arbitrary except that it is based on the English statute, and represents, perhaps, the most clearly recognized and most common diseases due exclusively to circumstances of occupation. But what has here been said as to the importance of registration of industrial diseases, if it be the correct view, applies equally well to any other occupational diseases. In other words, the fundamental principles of the matter make it highly desirable that all occupational diseases should be reported. While, therefore, the compulsion of law has been placed by the State only upon certain selected diseases, the opportunity of public service open to physicians is as wide as the whole field of occupational diseases. Is it too much to hope that physicians will see their opportunity for co-operation in this matter as broadly as the possibilities of the whole field, rather than the limited one covered by the law, so that the way shall be paved for rapid progress toward complete registration of all industrial diseases, as the necessary means to their control? Certainly the high character of the profession warrants expression of the hope at least.

Finally, there is one matter, which, while very much one of detail, is nevertheless one of such vital importance to the successful utilization of the knowledge which registration of occupational diseases will make available for the state as to warrant its mention here.

In what has been said in the foregoing it has been emphasized that registration of occupational diseases by physicians is the necessary means by which technical information which comes naturally to

physicians in the practice of their profession is to be made available for the state authorities. But it is absolutely necessary in this matter that the physician's technical information his diagnosis of the disease—shall be accompanied by information as to the occupation of the patient and the industry and establishment in which he is employed if the exact relation between the occupation and the disease is to be determined and the furnishing of this information is accordingly definitely specified in the law. Obviously this is asking the physician for something not necessarily a matter of knowledge in connection with his professional relations with the patient at all, so that the reporting law is requiring at this point that the physician shall take the trouble to secure information outside of his professional knowledge and useful to the state alone. It is probably for this reason that, as experience abundantly shows, physicians so often fail to exercise care in reporting this particular information in connection with registration of deaths. But it is of the most vital importance to the state that this should be done with care both in reporting deaths and in reporting occupational diseases. From the statistical point of view the value of all the information furnished largely hangs on this one thing. It is the necessary link by means of which the connection between disease and occupation may be established. Physicians cannot be too strongly urged, therefore, to exercise care at this particular point. Believe me, though it may seem extraneous matter from the medical point of view, and though it may cause what may seem unnecessary effort to secure it accurately, upon the physician's care at this point depends not a little the success of the present movement to establish a broad scientific basis for the control of occupational diseases.

INDUSTRIAL DISEASES DUE TO THE USE OF METALLIC POISONS AND THE MEASURES NEEDED FOR THEIR PREVENTION.*

By M. ALLEN STARR, M.D., LL.D., Sc.D.,

NEW YORK,

PROFESSOR OF NEUROLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY.

In many trades the workers are exposed inevitably to the dangers of poisoning by metals, especially by lead, arsenic, mercury, and phosphorus.

Lead is used in many industries and its ill effects on the body have long been recognized. In the smelting of lead ore at the mines, in the manufacture of red and white lead, in the use of paints, in the printing trade, in file-cutting, in enameling, in the manufacture of china and earthenware, in glass making, and in all work where paint is used, such as carriage and automobile making, shipbuilding, or house decoration, and among plumbers the exposure of the laborer is constant.

The common forms of lead poisoning—lead colic, lead tremor and lead palsy—are easily recognized, and are very serious as they are of such long duration. In my clinic, where such cases are common, it is rare to see recovery under six months—a long time for a man to be out of work.

It is not only these types which are of importance. The chronic poisoning by small amounts of lead, leading to a general state of malnutrition, pallor, anemia, ill health, and lack of strength and of mental capacity, is often overlooked. Many cases of gradual loss of vigor and so-called neurasthenia are actually due to chronic lead poisoning. This may manifest itself by chronic headaches, loss of eyesight, forms of neuritis, lack of ambition, and the impaired power of work and by psychasthenic symptoms. The blue line along the gums is a sign never to be overlooked.

These facts have been appreciated more fully in England where much legislation has been carried through for the protection of workers in lead. The efforts of the Home Office regulations and of medical inspection in Great Britain reduced the number of cases of lead poisoning between 1899 and 1906 one-half. The measures taken in factories where red and white lead are manufactured consisted in requiring that the walls be kept smooth and clean and free from dust, that the floors be made of cement and washed, that where dust containing lead was inevitable it be moistened by sprinklers, that the workmen be shifted frequently from the dangerous exposure to dust and fumes to less perilous departments, that they be provided with moist respirators to prevent inhalation of lead dust and with special overalls which are regularly washed, that bath houses be provided, that cleanliness be inforced, and that washing of the hands in a weak acetic acid solution before eating be insisted upon. The use of tobacco and alcohol is prevented so far as possible as they both predispose to lead poisoning. And an effort has also been made to prevent women and children from going into this industry as lead predisposes to abortion and stunts the growth of minors.

It was found in England that many cases of lead poisoning arose in the manufacture of glazed china. The glaze, which is a liquid, contains lead and when dried the articles are smoothed and cleaned. In this smoothing the lead dust gets into the air and is inhaled by the operators. In Staffordshire alone 50,000 persons are employed in this industry. In 1898 Professor Thorpe and Sir Thomas Oliver were appointed to see what could be done to prevent the enormous number of cases of lead poisoning. They ascertained that white and cream ware could be glazed by silicates without lead, and that the per cent. of lead could be reduced in other glazes from 20 or 15 per cent. to 5 per cent., and that the use of raw lead was most dangerous and should be avoided. They therefore recommended that the processes of manufacture should be changed. The manufacturers of course objected, but after investigation and arbitration the Home Office enforced the adoption of these measures and further prohibited women and children from working in the trade. As a result of this governmental supervision the number of cases of lead poisoning in the earthenware trade was reduced 70 per cent. in five years.* Overalls and respirators are worn, proper ventilation is required, the rooms are kept sprinkled and clean, and the operators are regularly examined medically and a health register is kept. Similar restrictions should be demanded in this country. In our manufacture of earthenware 10 per cent. of lead is now used and few precautions against poisoning are observed.

Another industry in which lead poisoning occurs is the manufacture of storage batteries, a paste of red lead and sulphuric acid being rubbed into the openings in perforated metallic plates. This employment has been considered dangerous in Germany and England, statistics showing that nearly 30 per cent. of the workers are poisoned and special

*Read at a meeting of the New York Academy of Medicine, January 4, 1912.

regulations in regard to the wearing of rubber gloves and to personal cleanliness, which is the chief preventive, are enforced there. In our factories these are neglected.

In the industries of file cutting, diamond cutting, the polishing of precious stones, glass and crystal, the enameling of iron work, especially bath tubs, in all of which lead is used; in all plumbing work, in the founding of type, in printing and type setting, and particularly in the use of paints there is always danger of lead poisoning.

Layet states that in France 111 industrial processes involve the use of lead, and Dr. Alice Hamilton states that in Illinois there are seventy industrial processes in which lead or its salts are handled which have caused lead poisoning. Painters who work indoors, those who scrape off paint from old objects before repainting, as in coach and ship-painting, and who mix paints are very subject to poisoning. I have talked with many painters on this subject and it is rare to find one who has not at some time suffered. I have seen two severe cases of lead paralysis, one fatal, in little children of a painter who had been allowed to play with paint. Plumbers have informed me that it is rare for a man long in the business to escape poisoning. Oxide of zinc may be substituted for white lead in paint, and in 1909 a law was passed in France making this compulsory after 1914. It is to be hoped that other countries will follow and forbid the use of lead in paint.

I fail to find any effort at instruction of these laborers as to the means to prevent the effects. If in every shop there were printed notices, or if to every worker notices were presented, or if in every labor union meeting notices were distributed containing directions, something might be accomplished. The need of using respirators when working in dusty or close rooms, the need of washing the hands in vinegar, the need of protecting the food from paint by holding it between bits of clean paper when washing is impossible, the need of the frequent use of saline laxatives and of applying for treatment as soon as the common symptoms of colic or headache are noticed, should be made plain by these means.

Such measures might be entrusted to labor unions, to the Board of Health, or to the Commissioner of Labor, but some one should undertake a campaign of education among the workers in these dangerous trades, and in factories some method of protecting operatives should be enforced.

The crying need of some such measures is shown by the fact that "of two factories engaged in the production of white lead in one of the central States, one, in which no effort was made to safeguard life, although employing only eighty hands, was compelled to renew virtually the entire working staff every ten weeks; the other, conducted on principles of humanity and civilization and employing twice as many hands, took on less than a hundred new workmen during the year." (MEDICAL RECORD, December 2, 1911.)

Dr. Alice Hamilton states that in 1910 in England, under the rules already mentioned, out of 1,320 persons employed in white lead works in Newcastle on Tyne only five cases of poisoning were reported; while out of 450 persons employed in Illinois sixty-three cases were reported, *i.e.* one in every seven. (*Jour. Amer. Med. Assoc.*, 1911, April 29.)

In lead smelting works almost all the operatives become poisoned sooner or later by the fumes containing lead if they remain at work more than a few months. This was formerly the case in Germany, but while there in 1885 with no regulations, 73 per cent. of workers were poisoned, in 1892 under regulation only 0.8 per cent. were affected. In one Austrian smelter the introduction of proper ventilation by erection of a tall chimney reduced the per cent. of operators affected from 70 per cent. to 3 per cent. (*Boulin Bull. de l'inspection du travail*, 1906.)

Laureck (Weyl, *Handbuch der Arbeitenkr.*) states that in Austria in lead-producing factories in 1886, 43 per cent. of the operatives suffered from poisoning, while after governmental supervision had been instituted in 1892 but 6 per cent. were affected. He also shows that 71 per cent. of all cases of lead poisoning occur in winter and but 29 per cent. in summer, a fact which proves that free ventilation and plenty of fresh air is a great preventive of such diseases.

If these facts are admitted it becomes evident that State supervision of the industries in which lead is used is imperative; that factories should be properly ventilated by forced drafts; that good warm bathrooms with hot water, free soap, and towels should be provided and time allowed operatives to bathe; that clean overalls and respirators should be furnished and their use insisted on; that medical inspection under the Department of Labor should be required with power to enforce the precautions recommended. The mouth should be washed before eating with a solution of sulphate of soda and the hands in a solution of nitro-hydrochloric acid.

These are regulations which are now enforced in England and all over the Continent. They are not considered by employers there unreasonable and they have resulted in a rapid diminution in the percentage of operatives thrown out of work by reason of poisoning and hence to a material saving both to the employer and the employee.

Arsenic is another poison whose effects are most serious. Its handling occurs in twenty-seven trades, all of which are dangerous. In arsenic mines and in the works where arsenic is reduced from the ore, in the preparation of arsenic for use in the arts, in the dyeing of wall papers and fabrics, in the curing of furs, and in the dyeing of rugs and many textiles by analine dyes, there is great danger of poisoning. The arsenic is given off in fumes or exists in fine dust which is inhaled.

The symptoms are more insidious than those produced by lead. Gastric and intestinal affections which become chronic are first noticed and these lead to a state of malnutrition, anemia and cachexia, rendering the person an invalid. Dark pigmentation of the skin, dryness and falling of the hair, and then various forms of paralysis due to multiple neuritis follow, and the person affected is useless for many months. The presence of arsenic in the urine where it can be easily detected is a positive proof of poisoning. Hence this examination is imperative in all cases of obscure disease developing in this class of workers.

Arsenical poisoning is not uncommon among the public. I know of one case at least where it was directly traced to wall paper. The patient was advised to remain in bed during the first three months of pregnancy in order to avoid a miscarriage. In view of this confinement her room was repapered and refurnished with a green fabric. In both paper and fabric arsenic was subsequently found. At the end of the second month she developed arsenical

multiple neuritis and for a year and a half was paralyzed and unable to walk, but finally recovered.

In 1899 a widespread epidemic of arsenic poisoning occurred in England which was traced to the beer manufactured in Salford and Manchester. This beer was brewed by the aid of "inverse sugar," or glucose, a substance in the preparation of which sulphuric acid is used. This acid was the source of the arsenic. Examination showed that the glucose contained four parts of arsenic to 10,000 parts and that the beer contained from 0.14 to 0.28 grain of arsenious acid to the gallon. Hundreds of persons were affected, many being paralyzed for months.

In the fur trade persons are exposed to arsenic. Out of forty-two samples of furs recently examined by an American chemist, eleven were found to be heavily loaded with arsenic, reaching 170 grains to the square yard. Such furs are dangerous to the wearer.

Knowledge of the dangers in these trades and in the use of arsenical papers, beers, or furs may lead to the adoption of such precautions as will prevent poisoning. In the factories preventive measures such as forced ventilation, exhaust pipes to draw off poisonous fumes, the use of respirators to prevent the inhalation of dust should be enforced and the operatives instructed in the dangers and in the need of great cleanliness. They should be careful to protect any cracks or sores on the skin from contact with arsenic.

Mercury is another poison dangerous to workers. In the mines where the metal is extracted by vaporization and subsequent condensation, little drops of metallic mercury are deposited on the persons and in the hair and clothing of the workmen, and being oxidized in the air the oxide is inhaled or swallowed causing poisoning.

In the preparation of barometers and thermometers workmen have to handle mercury. In the separation of gold and silver from various ores by means of an amalgam, mercury is used.

In the manufacture of incandescent lamps where mercurial pumps are used to cause a vacuum, in processes of gilding and bronzing, and in the silvering of mirrors, mercury is employed. Silk hats are dressed in an acid solution of nitrate of mercury, and the same process is used in dressing furs and in making some felt hats.

In everyone of these employments cases of poisoning are frequently reported. The poison causes gastric and intestinal symptoms, and ulceration of the gums with falling of the teeth and salivation. Tremor of a chronic character soon appears and general weakness with marked cachexia which may go on to paralysis.

The dangers of this toxic agent have been widely appreciated and in these factories considerable care is already taken to avoid the effects. Thus the process of silvering mirrors has been entirely changed in recent years and the danger there is eliminated. But in other industries much remains to be done in the way of forced ventilation, provisions for personal cleanliness, and personal instruction as to means to avoid toxemia. I see cases coming from the hat factories of Orange, N. J., every year where few precautions are taken.

Poisoning by *phosphorus* occurs in those industries in which matches are manufactured. This has been made the subject of a special investigation by Dr. Graham Rogers, the medical inspector of factories of the State of New York, in the report of Commissioner of Labor for 1910, where all the processes of manufacture are described and the dangers set forth.

About 600 operatives are employed in this state in this industry, but cases of poisoning are not very common as precautions have been taken in many of the factories to prevent them.

The attention of the public has been called so frequently to the dangers of workers in phosphorus, that in the chief factories of this state proper ventilation has been secured. Directions are posted up in various languages for the employees of the company, giving instructions as to the risk of poisoning and as to the methods of avoiding it. Washing facilities are ample and a dentist is employed by the company to examine the teeth and gums, as it is well known that with the earliest signs of poisoning appear a decay of the teeth and a necrosis of the jaw.

It is a fact that a harmless process of manufacturing matches has been discovered and that the match company which owned this discovery made it public so that it could be used by every company engaged in the business. This increases the cost of manufacturing about 5 per cent., but it is probable that public sentiment will enforce its adoption.

It is evident, therefore, from this review of diseases due to the use of metallic poisons, that much can be accomplished in their prevention by the proper regulations of the processes of manufacture by law. State supervision is absolutely needed and can only be secured when public sentiment is aroused to the need of it, and when measures can be carried through the legislatures for the protection of working people. These measures have been carried and enforced in England and on the Continent and it appears to be the duty of the medical profession at the present time to do all in its power, by exciting public sentiment, by the diffusion of general information, and by bringing personal influence to bear upon the members of the legislatures of various States to secure these results.

OCCUPATIONAL DISEASES OF THE SKIN.*

By JOHN A. FORDYCE, M.D.,

NEW YORK.

PROFESSOR OF DERMATOLOGY AND SYPHILOLOGY UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE skin both anatomically and physiologically is endowed with a relative amount of protection against the action of irritant substances. Cutaneous vulnerability is more or less an individual peculiarity, for while individuals are met with who are so sensitive to an irritant, be it physical, chemical, thermal, or actinic, that they react after a short exposure or contact by an acute dermatitis, many other people may handle the same agents with impunity. The majority of irritants met with in the trades do not of themselves evoke an eruption but rather act in conjunction with certain contributing factors. Those which come more prominently under consideration are a "special susceptibility," a delicate skin, or one presenting some congenital anomaly, as excessive dryness or ichthyosis; impaired gastro-intestinal, hepatic, or renal function; a depressed state of health, neglected hygiene of the skin, or a lowered resistance by a preexistent eruption.

Persons who exhibit a high degree of sensitive-

*Read before the New York Academy of Medicine Committee on Public Health, Hospitals and Budget, January 4, 1912.

ness are usually obliged to seek some other occupation for instead of acquiring an immunity an increasing susceptibility is established. Fortunately they are in the minority and it is more usual to see workers subjected to continuous injury only after a longer time develop lesions either from the summation effects of the irritant or because the resistance of the skin has been gradually undermined. After such a cutaneous outbreak there is frequently a tendency to acute exacerbations at regular intervals or when the occupation is resumed. In such individuals an eruption may persist for years.

As the skin responds to the most diverse irritants by the production of a catarrhal inflammation, it is not surprising that the commonest type of occupational disease should be an eczematoid dermatitis. This may vary in grade and intensity from an erythematous and scaling dermatitis to a vesicular and bullous eruption. As the condition becomes chronic infiltration of the skin takes place with scaling and fissuring. With the cutaneous defenses lowered, pus infection is frequently superadded.

By extracting the fat and macerating the horny cells the excessive use of soap and water reduces the resistance of the skin. They may then act as direct excitants or prepare the way for some other irritant, as washing powders, etc. Severe eczemas of the hands and forearms are seen in those whose occupation requires them to have their hands continually in water, as in the case of washerwomen, housemaids, barkeepers, etc. In my clinic at the University and Bellevue Hospital Medical College about two per cent. of the total number of new cases for 1911 constituted occupation dermatoses, of which nearly one-third were seen in persons whose vocations necessitated the frequent employment of soap and water and in some cases the various cleansing alkalis.

A warm moist atmosphere, such as laundresses work in, also causes a cystic condition of the sweat ducts of the middle third of the face, known as hydrocystoma. People exposed to heat, as cooks, stokers, firemen, etc., present various inflammatory processes and sweat eruptions like prickly heat.

In bakers a form of dermatitis of the hands and forearms is known as baker's itch. The exciting cause is probably the heat, although both the flour dust and a mite said to live in flour have been incriminated. Candy makers suffer from a similar eruption as well as impetiginous lesions. In a personal communication Winfield describes a dermatitis in sugar refiners which involves the hands, forearms, and legs and resembles an impetiginous scabies. It has been claimed that a mite found in raw sugar is responsible, but this lacks verification. Oliver states that in sugar factories a condition known as "lymphangitis of sugar makers" is sometimes found among the refiners and molasses stirrers. It is accompanied by slight constitutional disturbance and a crop of boils is a not unusual sequel. According to Gaillot the lymphangitis is a *Staphylococcus pyogenes aureus* infection. The organism is said to be found not in the freshly made molasses but in the residue, and that the temperature of the factory and the condition of the skin of the people favor its development.

Builders and masons sometimes develop an eczematous affection of the exposed parts of the body from the irritating effects of lime and Portland cement. In stone cutters an analogous condition is caused by the stone dust. A palmar dermatitis is also seen in brickmakers.

The resinous dust of certain hard woods, like teak, will occasionally set up a dermatitis in carpenters and joiners. In teak the exciting agent is believed to be an essential oil derived from the central part of the tree and present in the dust. The symptoms are sometimes very severe, the eruption becoming generalized and accompanied by vomiting. It may last for several months and is quite apt to recur on resumption of work.

The so-called polisher's itch of the forearms and hands met with in furniture polishers is attributed to the methyl or impure alcohols present in varnishes and polishes. Impure turpentine used for cleansing purposes and benzine likewise provoke an eczema of the hands.

Chemists are prone to inflammation of the hands and sometimes the face from handling various drugs and chemicals. Their skin often develops so marked a susceptibility that minute quantities or even fumes will call forth an outbreak. I have several times noted a similar anaphylactic condition in laboratory workers from formalin. Another familiar example of an eczema due to chemical action is that of the hands of physicians and nurses from the use of antiseptics, notably bichloride of mercury. These forms of dermatitis are very rebellious to treatment. An eruption of an erythematous and pustular type due to mercury is also met with among miners, smelters, and photographers.

The irritant action of arsenic on the skin is well known. In the arts and manufactures where its compounds are employed workers are attacked with eczema or ulcerative and gangrenous lesions, which may be present on the face, neck, and extremities, but more especially the genitals. In color works ulcers of the hands and designated "arsenic pock." The sulphide of arsenic which, with lime, is used in curing fur sets up a very severe dermatitis in furriers, not infrequently with persistent ulceration.

The use of the chromates in the arts and trades gives rise to an eczematoid eruption as well as ulceration of the skin and mucous membrane, which shows little tendency to heal.

Hydrofluoric acid, employed in the manufacture of glass, the bleaching of cane, washing of manure, etc., produces sores of the nasal orifice and gums and painful blisters and ulcers of the skin.

Electroplaters, who use a mixture of lime dust and olive oil in "finishing" and sour beer in the process known as "scratch brushing," are liable to an inflammation of the hands and forearms.

Printers, from contact with the various chemicals employed in their trade, often develop a chronic eczema of the hands and forearms.

Metal workers, either from the constant irritation of the dust or filings or from their direct cauterant action, suffer from various grades of inflammation to intractable ulceration.

In flax and linen workers various skin affections are reported, among them a follicular eruption due to the oils and irritating materials met with in this occupation. In Belgium many of the flax-workers show a peculiar abrasion and ulceration of the palmar surface of the hand. Fissures form, exfoliation takes place, and when the deeper structures are involved the condition simulates a syphilitic lesion. An eruption resembling smallpox has also been described on the forearm, arm, and face of the workers who remove the bobbins from the spinning frames. From the pressure and friction caused by pulling threads the people who engage

in this part of the work present callosities on their index fingers.

Callosities of the palms are also met with in laborers, engine drivers, etc. Among miners they form a special dermatosis called "beat hand." Painful thickenings develop over the regions where the handle of the pick makes greatest pressure, along the bases of the fingers, over the ball of the thumb, and outer side of the hand. The subjacent tissue becomes inflamed, and not infrequently is further complicated by suppuration. To this condition the term "keens" is applied.

Dyers and workers in aniline colors are apt to suffer from eczematoid and pustular eruptions on different portions of the body. The bad effects are not limited to those in this trade, but the wearers of clothing prepared with certain of the dyes may ultimately be the victims of a severe dermatitis. The black, red, and orange yellow pigments are particularly irritating, marked inflammatory reactions having been caused by socks, gloves, underwear and shoes so colored. I have also seen unusually severe forms of eczematoid dermatitis in barbers who had employed proprietary aniline hair dyes on their patrons. It is not an uncommon experience in dermatological practice to be consulted for a dermatitis of the face, neck, and ears which had followed the application of various of these hair dyes. In susceptible subjects the use of hair tonics may produce similar trouble.

The manufacture of chloride of calcium and chloride of sodium and potassium by electrolysis is sometimes attended by an erythematous and edematous inflammation of the face of the workmen resembling erysipelas. This is attributed to the hypochlorite of soda that is formed. With the subsidence of the acute process an acneiform eruption is left behind, the so-called chloracne, which is the commoner cutaneous malady met with in this occupation. It is characterized by the early development of blackheads followed by a grayish discoloration of the face. With inflammation and suppuration of the follicular glands pustules and boils appear on the face, chest, and back.

Tar and paraffin workers develop a similar eruption which may last several months and then change to the so-called "tar itch." This is accompanied by hyperkeratosis and increased activity of the sebaceous glands, forming plaques and crusts, with the further development of multiple warts, one or more of which degenerate into malignant growths. The disease affects chiefly the hands, forearms, and scrotum. It progresses slowly and in many instances no recurrence takes place after removal of the epithelioma. Oliver cites the case of a man aged 58 who had worked among coal-oil and tar products for thirty years. He presented numerous indurated patches, some of which had ulcerated, as well as multiple black warts and scars, the remains of old ulcers. His son, 27 years old, following the same employment, developed a malignant growth of the forearm which necessitated amputation. Metastases of the axillary and cervical lymphnodes took place, the patient succumbing to secondary carcinosis.

Cancer in chimney sweeps has been reported chiefly from England. The soot produces a chronic irritation of the skin and when retained in such regions as the folds of the scrotum causes warty growths which become epitheliomatous. In some instances the hands, arms, and thighs have been involved. The incidence of scrotal cancer has been markedly reduced by the use of machinery to clean chimneys.

It is reported that gardeners who employ soot for the protection of plants from slugs similarly show the effects of this irritant in the development of malignant growths of the hands.

Gardeners and florists not infrequently suffer from some form of inflammation of the hands and arms occasioned by contact with certain plants. It is estimated that between sixty or seventy possess this irritant action and the power to induce a dermatitis. The more familiar ones are poison ivy, poison sumac, primrose, chrysanthemum, and eucalyptus, the eruption varying from a simple erythema to marked swelling with the formation of vesicles and bullæ. Not only are the exposed parts involved but the affection may be carried by the hands or clothing to other portions of the body. It is probable, as in the case of rhus toxicodendron, that the active principle in the majority of these plants is an essential oil.

In individuals who follow an outdoor occupation the uncovered portions of the skin sometimes undergo peculiar degenerative changes. Under the name of sailor's skin Unna has described an affection which he observed chiefly in seafaring men. A diffuse cyanotic redness not unlike chilblain develops at first on the ears, adjacent parts of the cheeks and temples, the backs of the hands, and fingers. The skin then becomes mottled, pigmented, rough, and hard, and in places papillomatous. These warts may last for years and slowly undergo a malignant change. A similar condition is met with on the face, neck, and hands of people who follow agricultural pursuits. The cause is sought in the actinic rays. The effect of light on the skin is illustrated in x-ray workers, in whom, unless protected, the hands become the seat of a mild erythematosquamous eruption, more or less persistent, which is succeeded by pigmentation, telangiectases, and atrophic wrinkling. This condition may remain unchanged or keratoses be added which develop into epitheliomata.

Drivers and coachmen exposed to the rigors of the weather are often the subjects of the severer forms of rosacea. The use of alcohol, however, to which many of these people are addicted, cannot be wholly ignored as a contributing etiological factor.

Certain callings, notably those dealing with live or dead animals or their products, favor the development of parasitic diseases. Owing to the prevalence of pyogenic organisms local pus infections are not at all rare, especially in butchers, slaughter house men, and other individuals who handle dead animal matter. A generalized bullous dermatitis with a fatal termination has also been observed. The diseases which are more definitely identified with particular occupations, however, are tuberculosis, anthrax, glanders, and actinomycosis.

Inoculation tuberculosis occurs in its simplest form as verruca necrogenica or anatomical tubercle. It is encountered chiefly among medical students, physicians, hospital ward attendants, and butchers as a localized warty formation usually about the knuckles or other parts of the hand or forearm.

Anthrax is uncommon in this country but is very prevalent among animals, especially cattle and sheep, in certain parts of Europe and Asia. In man the disease occurs as the result of direct infection from such animals or their products. It is met with in the wool-sorting, wool-combing, and spinning in-

dustries, in horse-hair and brush factories, in stevedores, wharf-laborers, carters, farmers, shepherds, butchers, meat inspectors, and cattle salesmen. Infection takes place through the skin, the intestines, or, more rarely, the lungs. The internal form is known as wool-sorters' disease. Of the external, which is also the more usual, there are two varieties, the malignant pustule and malignant anthrax edema, the more fatal of the two.

Glanders, usually contracted from horses or asses, is seen almost exclusively in hostlers or those who have to do with these animals. It is rare in this country. The bacillus may gain entrance through the mucous membrane of the eye, nose, mouth, or respiratory tract, or the site of inoculation may be a lesion of the skin. Clinically the disease is divided into glanders and farcy according to whether the lesions of the mucous membrane or skin predominate. Both types present an acute and a chronic form.

Actinomycosis is endemic in cattle and more rarely affects horses, hogs, and other animals. In man the disease is seen in those who come in contact with such animals or handle fodder or grain, as farmers, coachmen, dairymen, millers, etc. The ray fungus is said to flourish on corn, hay, and cereal grains. Infection in man takes place through a carious tooth or lesion in the mouth and less often through the skin.

Sporotrichosis, a mycotic infection of the skin, occurs as subcutaneous nodules which soften and may or may not break down and form indolent ulcers and sinuses. They sometimes follow the line of the lymphatics and again the lesions may be widely disseminated over the body. The fungus, which probably gains entrance to the body through an abrasion or wound, is readily cultivated from the abscesses. The disease is met with spontaneously in horses and mules as epizootic lymphangitis, and hostlers, farmers, and other people who deal with these animals are liable to infection. The sporothrix has also been demonstrated on vegetables and these may form a source of inoculation to individuals who handle them.

Ringworm is one of the minor infections transmitted from horses, dogs, and other domestic animals to men and boys employed about stables or engaged in the care of such diseased animals.

Erysipeloid, an infection of the skin caused by poisoning from meats, fish, poultry, cheese, and similar animal products, is seen chiefly in butchers, fishmongers, poultry-dealers, and cooks. Crab bites are also a frequent cause. The disease is characterized by one or more areas of slowly spreading inflammation, the advancing border of which is festooned. It is usually confined to the hand and fingers.

In certain grain regions infested by a mite, *Pediculoides ventricosus*, an intensely itching urticarioid eruption is endemic among the farmers and laborers who handle sacks of wheat, barley, and other grains or straw harboring this parasite. Small epidemics have also appeared at different times from the use of mattresses made from straw on which the organism had made its habitat. To Dr. Jay F. Schamberg belongs the credit of priority in describing the affection in this country.

With the exception of certain well defined types ocupational dermatoses as a class have perhaps not received the attention they merit. It is possible that the influence of industries in the production of obscure maladies and sporadic cases of infection is more significant etiologically than usually credited. As pertinent to this an interesting case of leprosy was recently brought to my attention by Dr. Marcus Haase of Memphis, Tenn., and is cited here on account of its possible connection with the man's occupation. The patient was a native of Arkansas, sixty years old, and a furniture dealer. He had never been out of this country, nor indeed away from his own State, except on two occasions when he visited Philadelphia. Dr. Haase first saw him three years ago, at which time he made a diagnosis of tubercular leprosy. The disease had existed for six years. The man's work necessitated handling matting which he received in original packages from Canton, China. The patient's daughter is also a victim of the affection, having had the macular type for two years.

Dr. Haase's interest in this case prompted him to write to the American Consul in Canton, China, regarding the employment of lepers in the matting industry and, under date of December 4, 1911, received the following letter from Mr. Bergholz: "In reply to your letter of August 26, relative to the possibility of leprosy being carried to America in matting made in China, I beg to inform you that I have made extensive inquiries here, among foreigners and Chinese alike, and I am convinced that lepers are not allowed to engage in the weaving of matting. I am told by a large matting exporter that it is physically impossible for a leper to do this sort of work, and the probability that they are never permitted to engage in the industry is further strengthened by the fact that in those districts where Canton matting is made lepers are well-nigh segregated from the rest of the people—in fact, in places where, unlike Canton, there is no isolation station they are driven out to shift for themselves. At Do Sing, on the West River, there is a large leper colony, the members of which live in small boats and subsist chiefly, if not entirely, by begging. It cannot be ascertained here whether or not they engage in any industry. At Canton there is an isolation station accommodating about 600 lepers, many of whom are allowed into the streets to beg and a very few to make hemp rope, bambooware, and woodware, all of which articles, I understand, find their way into the local market. The inmates receive fifty cash (about two cents gold) a day from the Government and one cotton garment a year and are left to eke out their subsistence with the proceeds of their industry and begging. That there is need of further action before the degree of leper segregation approaches completeness at Canton may be inferred from the fact that the subject was discussed in the Provincial Assembly during its second annual session in 1910, and recommendations made that further steps be taken toward more perfect isolation. You will find a more comprehensive article on leprosy in China in Prof. J. Dyer Ball's 'Things Chinese,' from which it may be inferred that in Swatow, at least, unless recent steps have been taken to alter the conditions therein stated, lepers are allowed to mingle with the people and isolation is unknown."

In view of the fact that it is claimed by Duval of New Orleans and others that the lepra bacillus might live for two years exposed to the air, an observation like Dr. Haase's deserves careful consideration.

The author acknowledges his indebtedness to Dr. Thomas Oliver's work "Diseases of Occupation" (E. P. Dutton & Co., 1908) for much information concerning the various industries.

8 West Seventy-seventh Street.

ON THE USE OF SALVARSAN IN SYPHILIS OF THE NERVOUS SYSTEM, BASED UPON A STUDY OF EIGHTY CASES.*

FROM THE NEUROLOGICAL SERVICES OF THE MOUNT SINAI HOSPITAL AND THE MONTEFIORE HOME.

By B. SACHS, M.D.,

AND

I. STRAUSS, M.D.,

NEW YORK.

It is not an easy matter to arrive at a definite conclusion regarding the effect of a new form of treatment upon the acute and chronic diseases of the central nervous system. During the past year we have endeavored in hospital and in private practice to give Ehrlich's new remedy an impartial trial. Ehrlich himself was at first sceptical as to the possible use of salvarsan in syphilitic diseases of the nervous system; in print as well as in personal communication he expressed great hesitancy, and even fear, as to the employment of this drug. It was for this reason that for the first few months we employed very small doses, which Ehrlich was kind enough to send us in special tubes, and it was only after full justice was done to Ehrlich's suggestions that we proceeded to employ the new remedy in its full dosage. Our entire experience has shown that there is no more reason to fear the drug in syphilis of the nervous system than in syphilis of any other organs of the body, and it is well to record at the very outset that, if we could except a very few complications due to imperfection of technique in our earliest cases, we have not observed a single nerve or constitutional disorder which could be attributed to the use of the drug.†

Of the recurring specific manifestations (the *Neurorecidive* of the Germans) or of the complications which have been reported as following upon the administration of salvarsan, we have seen absolutely nothing. In this our experiences tally absolutely with those of Alt and Nonne; and Ehrlich has recently emphasized the point that these neural recurrences were to be expected in the early secondary stage of infection. Such developments as we had occasion to note—convulsions in one case, repeated attacks of hemiplegia, keratitis, and in one instance progressive optic atrophy—could in no wise be connected with the administration of the drug, and the complication was in each case to be interpreted as an incident in the natural course of the disease.

Before recording the exact results and the impressions, rather than the conclusions, based upon a year's experience, a word regarding the method employed. Both the intramuscular and the intravenous methods have been given a fair trial. Intramuscular injections have been given by using the arsenic preparation together with iodipin. We have used four or five c.c. for each dose of four, five, or six tenths of salvarsan, and have found that the injection of this mixture through a previously dried and heated needle caused very little trouble. There is no reason to limit the amount of iodipin, as some writers have advised, and we have felt that, by using a somewhat larger quantity of iodipin, a more diffuse depot could be formed, which was of no disadvantage to the patient. These intramuscular injections have the great advantage that they can be given in the office or in a private laboratory, and that the patient can be sent home at once, and is not likely to be disturbed in his daily routine. Whether the effect of these intramuscular injections is as marked as that of the intravenous injection, as applied to diseases of the nervous system, it is difficult to determine, since the effect of both is so largely negative. The relative merits of the two methods must be decided by those who are called upon to treat the earlier stages and the general manifestations of constitutional syphilis. In the wards at the hospital, and whenever practicable in private practice, we have given preference to the intravenous method. The technique, while it must be carried out with great precision, is such as every practitioner, and surely every neurologist, should acquire. If the solution is carefully prepared,* kept at a proper temperature, if the needle is introduced with equal care, and if normal salt solution is allowed to flow into the veins before the introduction of the salvarsan, there is little to fear. As a matter of fact, there is but one difficulty, and that is in introducing the needle in such a way as not only to enter the vein, but not to pass out of it again, and to hold the needle so steadily during the entire procedure that it is not unconsciously pushed through the wall of the vein opposite to the one which was punctured by the needle. If the vein cannot be punctured subcutaneously it is well to expose it by incision.

In every case, both at the hospital and in private practice, the Wassermann reaction of the blood and, if possible, of the cerebrospinal fluid, was taken. Whenever it was found positive we proceeded at once with the injection; if found negative—and it should be remembered that in a great majority of the cases after mercurial treatment it is negative—the history of the case was again well considered, and, if on clinical grounds the diagnosis of syphilitic disease was probable, the injection was given. We still consider that a purely clinical diagnosis of syphilis of the nervous system may be as certain as the diagnosis given us by the laboratory. Of course, a positive Wassermann reaction in the blood or cerebrospinal fluid, or a marked lymphocytosis, implies a more or less active specific process, and in such cases the salvarsan treatment would be applicable beyond a doubt. We are also in favor of repeated courses of treatment until the Wassermann reaction becomes negative, or until marked improvement takes place in the clinical symptoms. After giving one or, at the utmost, two full doses of salvarsan we have continued the administration of mercury and iodides.

Our impressions of the effect of salvarsan in syphilis of the nervous system are based upon a series of eighty cases.† This does not include cases in which the method has been employed for syphilis of other organs, or of cases in which the injections were given even if the diagnosis of syphilis of the nervous system was somewhat doubtful. Taking all these cases together, the remedy was applied in 18 cases of tabes, 7 of undoubted general paresis, in 30 cases designated as lues cerebri or cerebrospinal

*Read in part at a meeting of the New York Neurological Society, November 14, 1911.

†Since writing the above we have had one case (No. 43) of severe arsenical poisoning (hemorrhagic enteritis, auricular Zooster, severe ulcerative stomatitis, and moderate nephritis) following the second intravenous injection.

*We have had most satisfactory results since the adoption of Ehrlich's suggestion that only *freshly distilled* water be used.

†We are indebted to Dr. I. Abrahamson for the records of his cases at the Montefiore Home and for his willing cooperation

lues, in 14 cases of lues spinalis, in 2 cases of syphilitic epilepsy, and in 9 cases of constitutional lues with nerve symptoms, such as headaches, optic neuritis, specific pupils, and the like.

The experience thus far gained leads us to state that the course of the disease has not been markedly affected in a single case of tabes, although some improvement has taken place in one or the other of the symptoms. This is particularly true of the pains, of the vesical control, and of the ataxia, and, above all, of the recovery from complete loss of sexual power. We have the distinct impression that the disease has remained stationary in a number of instances, while in some others it has progressed rapidly in spite of the administration of salvarsan. All this could be said with equal truth of the behavior of the cases under mercurial treatment and in some cases in which no treatment whatever had been attempted. There has been no change in the pupillary reflexes, in the behavior of the deep reflexes, or in any of the objective symptoms.

Let us refer to a single case a little in detail as showing what the drug can do and what disappointment there may be, after all, before a long period of time has elapsed. A gentleman from the West, who had been off and on under observation for at least five or six years, had a specific chronic myelitis for which he had had continuous mercurial and iodide treatment, partly at Hot Springs, Ark., and partly at Aix-la-Chappelle. Clinically he was suffering from a spastic paraplegia, with some slight involvement of the bladder and with complete loss of sexual power. Hearing of the new form of treatment, he went to Europe in 1910, and in September of that year managed to see Prof. Ehrlich himself, who referred him to Alt for treatment. After the first intramuscular treatment he got worse; after the second (0.3) a very marked improvement set in. He returned in January, 1911, enthusiastic as to results. As a matter of fact, he walked far better than I had seen him walk in years; he looked well, and was satisfied with the return of sexual power which had been absent for many years. The improvement lasted for about six months; he returned in March, 1911, complaining again of soreness of the left leg and that his gait had lost its spasticity. His physical symptoms were completely unchanged. He developed a slight heaviness of speech, but he claimed that there was less fatgue than in former years and that the sexual power was maintained, and thinks the salvarsan injections have done him good. I saw him again November 8, just one year since the first salvarsan injection. During the last four weeks he has shown a slight mental depression and complains of his memory being poor, sexual power not being better than before the salvarsan injections. He was, however, so much impressed with the effect of the drug that he was ready to sail again to have another test of his blood made abroad, and if Alt advised another salvarsan injection he would be willing to submit to it.* I had no reason to oppose his plan. Such an experience is more or less typical of many others that we have had—a temporary improvement immediately after the treatment, relapses later on, renewed improvement, and a continuous alternation between recoveries and relapses.

In spite of the disappointing results of this new form of treatment, we are by no means ready to discard it, but since, if properly administered, it may be considered harmless, we shall continue to employ it, particularly in association with sublimate injections.

In view of what was said in the earliest literature on "606," it may be well to state that in not a single instance has the optic nerve been unfavorably affected by the use of salvarsan. In the one case of tabes with optic atrophy, in which blindness followed in spite of the salvarsan treatment or after it, the nerve was already so far atrophied that complete blindness was inevitable and the treatment was only given at the insistence of the patient and his friends.

In general paresis the impressions received were almost identical with what has just been recorded regarding tabes. In not a single instance could we claim that the disease has been cured, and, even after a surprising remission had followed the administration of the drug, the period that has elapsed is altogether too short to warrant more definite statements.

In at least two cases of the seven a thorough remission followed, lasting a number of months, but at the end of that time a further progression of the symptoms has occurred—the very thing which we are accustomed to observe in untreated cases and in patients who have received the full course of mercurials and iodides. It can hardly be put down to the discredit of this new remedy that it has accomplished so little in tabes and general paresis It was not supposed to accomplish much except in those conditions in which spirochetes were still present in the blood, and it was only an afterthought, a wholly natural one to be sure, that the attempt was made to employ the drug in parasyphilitic and metasyphilitic conditions. On the other hand, in several cases we have observed the most marked improvement, not directly upon the administration of salvarsan, but after a course of sublimate injections or inunctions given about a week after salvarsan had been exhibited. We employ in this class of cases both salvarsan and the mercurial preparations, in the belief that they supplement each other. It would not be conceivable that the drug should affect the degenerated tissues of the brain and spinal cord. It appears to us to be wise to employ salvarsan in the earliest stages of tabes, general paresis, and of cerebrospinal lues, to prevent the occurrence of purely specific complications, and possibly to check the further progress of the disease.

In the more active forms of brain and spinal-cord syphilis—in those that we have designated lues cerebri and lues cerebrospinalis—the effect of the drug has not been so disappointing. In a number of these, distinct improvement has followed upon the use of salvarsan. This has been particularly noticeable in the cases of brain syphilis complicated by purely cerebral symptoms. The somnolence, the headaches, the depression—which are so common in cases of brain syphilis, and the various forms of palsy, have disappeared after the treatment was given, and, as will be shown in the completely tabulated histories, improvement followed so rapidly in some instances that it must be attributed to the influence of the drug. The same is true, and to a greater extent, in the cases of purely spinal syphilis. In this group of cases improvement has followed more promptly upon the use of salvarsan than we have experienced in former years upon the use of iodides or mercurials.

*The patient again reports improvement (January, 1912) after two intravenous injections of 0.15 each

BRIEF SUMMARY OF CASES.

No	Age	Diagnosis	Wassermann	Treatment	Remarks
1	48	Lues cerebrospinalis	Not taken	Dec 18, 1911—0 4 intravenous	Claims improvement in vision (optic atrophy)
2	30	Cerebral lues (basilar)	Positive	Oct 11th Intravenous 0 4 Oct 27, 29, 31 Deep injections of bichloride Referred to dispensary	Somnolence, severe headaches Marked improvement, somnolence disappearing One convulsion 14 days after injection Patient appears psychically well (Sachs)
3	44	Cerebral lues	Negative (Blood and c s fluid)	Oct 12th 2 mercurial injections Sept 2d Intravenous injection 0.4	Gastric acidity Lymphocytes, 92%, Polynuclears, 8%, condition unchanged
4	34	Cerebrospinal lues Left hemiplegia (short duration)	Positive	June 12th One Salvarsan 0.6 intravenous.	Discharged ten days later, almost well Marked improvement. Infection 6 years previously
5	33	Cerebrospinal lues General paresis (?)	Positive (Blood and c s fluid)	July 28th—Intravenous 0 6. Aug 8th—Intramuscular 0 6 Followed by 12 sublimate injections. Specific lymphocytosis	Dr Harris reports: "Mental condition still suspicious of general paresis, but markedly improved" (Late in Dec , 1911, recurrence of speech disturbance and rapid development of symptoms of paresis)
6	45	Cerebrospinal lues Left hemiplegia	Slightly positive	Feb 27th—Intramuscular 0 3 Mar 17th Intravenous 0 4.	Infection 4 years previously Gumma on shin slightly diminished after treatment Marked temporary mental improvement followed by mental deterioration
7	37	Cerebral lues	Positive (Blood, weakly) (C S fluid, strongly)	Feb 8th Intramuscular 0 6 (marked lymphocytosis) Feb 27th—Intrascapular 0 3	Specific infection 13 years ago Marked mental improvement immediately following injections
8	25	Cerebral lues Right hemiplegia	Negative	Two months before admission intravenous "606" followed by 60 daily mercurial inunctions. In hospital and dispensary 10 additional sublimate injections	Infection 3½ years previously General condition improved Intravenous injection followed by marked improvement
9	59	Cerebral lues	Negative	July 21st Intravenous 0 6 Aug 8th—Intramuscular Aug 21st to Oct 18th 12 bichloride injections.	Marked improvement in mental symptoms Physical symptoms not altered
10	50	Cerebrospinal lues	Negative	12 Bichloride of Mercury injections in hospital and dispensary.	Infection 34 years ago Marked improvement; returned to work
11	45	Left hemiplegia	Positive (Blood and c s fluid)	July 20th Intravenous 0 6 Aug 5th—Intravenous 0 4	Infection 2 years previously Improvement in paralyzed hand and in face Was considered much improved
12	33	Left hemiplegia	Negative (after treatment)	June 8th Intravenous 0 6. June 19th—Intramuscular 0.3, followed by 23 injections of Bichloride of Mercury	Infection 4 years ago Several attacks of hemiplegia, right and left, improving under ordinary specific treatment Improvement more marked after second intramuscular injection
13	40	Cerebrospinal lues, right hemiplegia; right ptosis.	....	15 injections of Mercury.	Marked improvement; disappearance of all symptoms.
14	27	Cerebral lues	Negative (Before and after treatment)	1910 12 sublimate injections in 2 series of 6 Dec , 1910, to Mar , 1911—2 intravenous injections	Specific infection 3 years ago Previous attack of aphasia and hemiplegia; intense headaches; depression Knee jerks subnormal Complete recovery.
15	10	Hereditary lues Left hemiplegia		Treatment given by Dr Fordyce	Seen with Dr. Fordyce Symptoms—Keratitis, iritis, dactylitis, deafness. Attack of right hemiplegia with unconsciousness at 2 years Ten months later another stroke on same side. Has convulsize seizures
16	36	Cerebral lues	Negative after injections	Dec 29th, 1911—Intravenous 0 6	Unequal pupils, transitory diplopia; headaches, vomiting Improved markedly
17	?	Cerebral lues	Strongly positive	Mar 11th—Intragluteal injections 0 3 Mar. 18th—Intragluteal injections 0 3 May 18th—Intragluteal injections 0 3 Sept 7th—Intragluteal injections 0 5	Intense headaches and inability to do work with comfort for years Specific infection 14 years ago. Feb., 1911, and ever since, has reported complete recovery from former troublesome symptoms Is active in practice and most enthusiastic in his comment on the effects of treatment. Return of old-time energy; head perfectly clear Sept. 7, 1911—Complains of slight return of symptoms. In July had squamous eruption which disappeared after inunction treatment of 5 days
18	51	Hemiplegia. Arteriosclerosis. (Possibly specific)	.....	Feb. 19th—Intragluteal 0 3.....	No effect
19	27	Frontal headaches, left optic atrophy. Temp hemianopsia	Blood positive C S fluid; globulin cytology and reaction negative	Nov 11th, 1911—Intravenous 0 6 Dec 13th, 1911—Intravenous 0.6.	Reports marked improvement after 2 days
20	37	Lues cerebri. Diplopia, headaches; loss of speech (transitory)		Feb 29th—Intravenous 0 3 Mar 17th Intravenous 0.6 Nov 1st—Intravenous 0 5 23 sublimate injections (15 before admission).	Chancre 7 years ago Improved considerably after injections Also reports improvement after intravenous injections
21	44	Lues cerebri et cerebrospinalis	Negative ...	Oct 11th—Intravenous 0 6 ...	No change
22	40	Lues cerebri et cerebrospinalis	Blood negative	Apr 11th—0.6 intravenous	No change
23	50	Lues cerebri et cerebrospinalis	Blood negative	Mar 16th—Intravenous 0.3 Sublimate injections	Memory and speech improved Died of intestinal obstruction
24	24	Lues cerebri et cerebrospinalis	Blood positive.	Mar 10th—Intravenous 0.3. 9 salicylate injections.	Presented symptoms of cerebellar neoplasm; markedly improved, optic neuritis disappeared; returned to work
25	68	Lues cerebri et cerebrospinalis	Blood positive. C S fluid negative.	Sept. 2d—Intravenous 0 6	Glycosuria, 2 days following injection gangrene of toe; death from sepsis; glycosuria disappeared after injection
26	52	Lues cerebri et cerebrospinalis	Blood positive C S fluid negative	Oct 28th—Intravenous 0.6. Sublimate injections, and then Nov 9th—Intravenous 0 3	Marked improvement in mentality and cessation of syncopal attacks Second injection followed by rapid return of symptoms; asthenia and death

BRIEF SUMMARY OF CASES.—*Continued*

No	Age	Diagnosis	Wassermann		Treatment	Remarks
27	43	Lues cerebri et cerebro-spinalis	Blood positive fluid negative	C S	Oct 27th—Intravenous 0 6 Sublimate injections and inunctions Nov 9th—Intravenous 0 6	Symptoms of hemiplegia alternans superior, recovery of leg and of ophthalmoplegia externa and improvement in mentality
28 *	35	Lues cerebri et cerebro-spinalis	Blood positive fluid negative	C S	Sept 1st—Intramuscular 0 6 Sublimate and inunctions Oct 27th—0 4	Symptoms of intracranial pressure, transitory hemianopsia, glycosuria, dementia, recurring state of stupor All disappeared after treatment but have reappeared at time of report
29	50	Lues cerebri et cerebro spinalis	Blood positive fluid positive	C S	May 16th—Intravenous 0 4 June 22d—Intravenous 0 6 Then sublimate injections	Sight, hearing and general condition markedly improved. Post-neuritic atrophy of both eyes with complete amblyopia of one eye and improvement in vision of other eye
30	26	Lues cerebri et cerebro-spinalis	Blood positive		Aug 10th Intramuscular 0 6	No improvement
31	38	Specific Myelitis (Tabic type)	Negative		Mixed treatment Salvarsan given	Specific infection in 1896, mixed treatment Shooting pains, lively knee-jerks; some ataxia
32	41	Specific myelitis	Negative		Continuous mercurial and iodide treatment had been given, followed by improvements and relapses Sept, 1910—Intramuscular 0 2 Three weeks later Intramuscular 0 3	Under observation since 1907 Great variation in symptoms Had been given continuous mercurial and iodide treatment followed by improvements and relapses Treatment at Hot Springs, Arkansas, and at Aix la Chapelle At first got worse, then a very marked improvement Returned in Jan, 1911, enthusiastic as to results Spastic ataxic gait much improved; return of sexual power In March, 1911, complained again of soreness of left leg; gait lost its elasticity; both pupils react; knee-jerks gone. Condition very much the same as in former years Sept, 1911, occasional heaviness of speech, much less fatigue than in former years, sexual power maintained Thinks Salvarsan injections have done him good Optic nerves normal Nov 8th—(one year since Salvarsan injection)—In last 4 weeks slight mental depression; complains of poor memory; sexual power not any better than before Salvarsan injections
33	28	Specific paraplegia			Feb 17th—Intramuscular 0 2 Feb 19th Intramuscular 0 2 Feb 24th Intramuscular 0 2	Marked improvement in spasticity Some relapse after 6 months
34	53	Lues spinalis Spastic paraplegia (with bladder symptoms)	Positive		Specific treatment for years May 1st, 1911—Intramuscular 0 5 Followed by slight swelling	Infection 25 years ago, no improvement, symptoms slightly progressive
35	45	Lues spinalis, spastic (Some bladder involvement and much paralysis)	Positive		Apr Intramuscular 0 3 April—Intramuscular 0 3 Followed by necrosis	No improvement
36	26	Lues spinalis incipiens (Const lues)	Negative		Nov 6th, 1911 Intramuscular 0 5 Preceded by thorough mercurial and iodide treatment	Weakness of left upper extremity; slight hemi-hypaesthesia Too early to report result
37	56	Lues spinalis (Tabic type)	Blood positive Cerebrospinal strongly positive		Nov 6th, 1911 Intravenous 0 5	Shooting pains; increased reflexes; Argyll-Robertson pupils Reports improvement after injections surely subjective
38	45	Spastic paraplegia	Positive		Nov 7th, 1911 Intravenous 0 5. Dec 10th, 1911 Intravenous 0 4	Reports less stiffness after injection
39		Complete paraplegia during pregnancy	Positive.		Intramuscular injection 0 6 Intravenous could not be given	Some improvement after two months.
40	42	Lues spinalis	Blood negative. C S fluid positive		Apr 8th 0 6 Apr 11th—Intravenous 0 4	Spastic paraplegia, no improvement
41	38	Lues spinalis	Blood negative		Nov 11th Intravenous 0 4	Paraplegia and distinct sensory disturbances Bed-sore followed immediately after first injection No improvement
42	56	Lues spinalis	Blood negative C S fluid negative		Apr 11th Intramuscular 0 4	Slight improvement in spasticity
43	46	Lues spinalis	Blood positive		Oct 11th, 1910 Intravenous 0 4 Feb 23d, 1911 Intramuscular 0 6 Mar 23d, 1911 Intravenous 0 6, and sublimate injections	Pachymeningitis cervicalis; some improvement in power, lessening of pain
44	40	Lues spinalis	Blood positive C S fluid negative		Dec 18th, 1911—Intravenous 0 6 Dec 28th 1911 Intravenous 0 6	Acute onset commencing with paraplegia and later followed by involvement of arms Was improving when Salvarsan given
45	50	Locomotor ataxia	Blood negative C S fluid negative		Mar 20th—Intramuscular 0 3 Mar 27th—Intramuscular 0 3	Not improved
46	48	Locomotor ataxia			Feb 12th Intramuscular 0 1 Feb 18th Intramuscular 0 2 Mar 3d Intramuscular 0 6	Some improvement in general condition
47	38	Tabes dorsalis Ocular motor palsy	Positive		June 26th Intravenous 0 6 July 3d Intramuscular 0 6 At Dispensary 14 injections of Bichloride	Two days after intramuscular injection marked improvement; improvement in some of the complicating symptoms followed series of 14 mercurial injections.
48	43	Tabes dorsalis	Positive		Sept 7th Intravenous 0 5 (Dr Fordyce) Eight weeks later another	Initial infection 25 years ago Improvement in pains, condition otherwise stationary
49	37	Tabes dorsalis with optic atrophy			Feb 22d Intravenous 0 1 followed by 0 2 Intragluteal at intervals of 2 weeks	No change in symptoms Optic atrophy progressive, but rate of progression not more rapid than before treatment
50	31	Tabes incipiens (Pupils react Knee-jerks absent)			Mar 2d Intragluteal 0 3 Mar 4th Intragluteal 0 2 Preceded by 15 sublimate injections	No influence on symptoms Beginning loss of vesical control

*Since writing the above patient has died and autopsy revealed a neoplasm of the optic thalamus

BRIEF SUMMARY OF CASES.—*Continued*

No.	Age	Diagnosis	Wassermann	Treatment	Remarks
51	40	Tabes psychic depression	Strongly positive	Twenty-eight sublimate injections Mar 4th, 1911 Intragluteal 0.2 Mar 18th, 1911 Intragluteal 0.3	Slight albuminuria following S. injection Symptoms stationary except beginning loss of vesical control
52	49	Tabes (stationary)	Negative	Mar 4th, 1911 Intramuscular 0.3 Mar 14th, 1911 Intramuscular 0.3 Apr 29th, 1911 Intramuscular 0.4 During former years repeated courses of sublimate injections	No effect upon symptoms Clinical condition stationary for years
53	42	Tabes dorsalis incipiens	Negative (Wassermann and Noguchi)	Apr 14th, 1911 Intramuscular 0.2 Apr 18th, 1911 Intramuscular 0.4 Preceded by 10 sublimate injections 6 months previously	Feels distinctly benefited by "606;" less Romberg, less shooting pains No return of sexual power Initial infection 22 years ago
54	46	Tabes with psychic symptoms and ocular palsies	Positive (9 mos ago)	Apr 27th, 1911 Intramuscular 0.5 Apr 13th, 1911 Intramuscular 0.4 First injection followed by iritis, has had several previous attacks, present attack subsided rapidly Much specific treatment for many years	Infection 14 years ago, went to Europe, general improvement
55	44	Tabes dorsalis	Positive weak	May 18th, 1911 Intragluteal 0.3 May 25th, 1911 Intragluteal 0.3	Has had sublimate injections, mercurials and iodides for 4 years under immediate supervision No change in symptoms, very slow progression
56	39	Tabes dorsalis	Positive	In 1909 and 1910 several courses of sublimate injections (14 in all) May 30th, 1911 Intragluteal 0.2. June 6th, 1911 Intravenous 0.3	Better control of bladder, feels improved, no untoward symptoms after treatment
57	31	Tabes dorsalis with Epilepsy	Strongly positive	Oct 9th, 1911 Intravenous 0.4 Oct 9th, 1911 Intramuscular 0.4 Followed by 8 sublimate injections	No convulsive seizures since Salvarsan injections, looks better and brighter, feels much benefited
58	40	Tabes dorsalis	Strongly positive	Nov 28th, 1911—Intravenous 0.6 Sublimate injections to be given	Chancre 17 years ago. Much mercurial treatment in former years, chiefly salicylate treatment. Disease distinctly progressive
59	50	Tabes dorsalis	Positive.	Intramuscular 0.3 0.3 Intramuscular by Dr Mailhouse	Reports improvement in "dizziness, bladder symptoms and ataxia"
60	25	Tabes dorsalis	Negative (blood and c. s. fluid).	Oct 24th, 1910 0.6 June 14th, 1911 0.3	Ptosis disappeared, diplopia likewise
61	55	Tabes dorsalis	Negative (blood and c. s. fluid).	Nov 3d— Intramuscular 0.3	Improved, general condition
62	43	Tabes dorsalis	Positive (blood)	Sept 21st—Intravenous 0.6 Sept 30th—Intravenous 0.6 Oct 15th, HCCL2 injections.	Dizziness and somnolence disappeared
63	45	Tabes dorsalis	Blood positive	Dec 1st, 1911 Intravenous 0.6 Dec 13th, 1911— Intravenous 0.4	Somnolence and depression much improved Third attack of depression in 6 years.
64	52	General paresis	Positive	Sept 10th—Intravenous 0.4, followed by 12 bichloride injections Sept 17th - Intravenous 0.6	No improvement
65	46	General paresis	Positive	"606" given. Two intramuscular injections followed by mercurial inunctions and iodide	Five years ago gumma in nose In summer of 1910 became paralyzed No distinct benefit from treatment as reported by Dr Goldstein
66	38	Pseudo paresis luetica (Possibly G. P.)	Positive	Mar 7th—Intrascapular 0.3 Mar 20th Intragluteal 0.6	Very marked change in symptoms Distinct clearing up mentally; subsidence of excitement; bed-sore gradually healed, but case has shown marked remissions under all forms of treatment
67	40	General paresis (incipiens)	Positive	Mar 8th Intramuscular 0.2 Mar 22d—Intramuscular 0.3 Apr 1st—Intramuscular 0.3 Preceded by iodide treatment	No effect, symptoms have been steadily progressive
68	...	Incipient paresis or pseudo-paresis luetica	Positive	Nov. 7th, 1911—Intravenous 0.5, Dec 21st, 1911—Intravenous 0.6	
69	18	General paresis (juvenile)	Blood, positive Fluid, negative.	Oct 27th—Intravenous 0.6 Nov. 9th—Intravenous 0.2	Improved in mentality
70	38	Vague spinal symptoms Syphilidophobia Constitutional lues.	Negative	Feb 28th—Intrascapular 0.8 Followed by numerous sublimate injections Mar 25th—Intrascapular 0.6	No development of other symptoms Has irregular specific pupil No untoward effects from injection.
71	50	Lues, specific pupils, headaches.	Strongly positive	Intravenous 0.2, followed by swelling indurated mass which had to be removed by operation.	Infection 2 years ago; widower Immediate and vigorous treatment at Hot Springs, Ark., and at St Blasien Improvement as regards headaches.
72	42	Specific pupils	Positive	May 14th 1911—Intramuscular 0.4 May 19th, 1911—Intramuscular 0.3 Followed by 6 sublimate injections in Sept., 1911	No change
73	35	Specific pupils	Positive	Oct., 1911, a course of 6 sublimate injections Nov 9th, 1911— Intramuscular 0.5	No change
74	36	Specific vertigo	Negative	Nov 3d, 1911—Intramuscular 0.5	(Too early to report results)
75	36	Constitutional lues Dipsomania	Positive.	Nov 18th, 1911—Intravenous 0.3 Has had several courses previously of sublimate treatment	No distinct effect as yet
76	28	Constitutional lues	Positive (blood) Positive (c. s. fluid)	Oct 5th Intravenous 0.4	No improvement, evidences of pulmonary tuberculosis
77	27	Constitutional lues	Positive (blood)	Mar 8th—Intravenous 0.6	No improvement
78	...	Constitutional lues (fear of paresis).	Positive	Intravenous 1.2 given by another physician several months ago.	At present only specific pupils

BRIEF SUMMARY OF CASES.—*Continued*

No.	Age	Diagnosis	Wassermann	Treatment	Remarks
79	31	Specific epilepsy	Positive Aug., 1909 and May, 1910	Oct., 1909, to Christmas, 1910, 23 injections of bichloride; after that salicylates and mercury. Two Intravenous injections (dates not recorded) followed by several courses of sublimate injections	Specific infection 5 years ago. Epileptic attacks without consciousness at varying intervals. Incapacity for work during entire period of 1910. Marked diabetes insipidus, sleeplessness, general mental depression. Agarophobia, specific pupils. Recovery from psychic depression. Unable to ascertain whether he has been able to return to work
80	31	Idiopathic epilepsy. (Intercurrent syphilitic infection)		Nov. 29. Intravenous 0.5. Intravenous 0.4	Dec. 8. Had almost daily convulsions although under bromides. Since last injection none up to date, Dec. 17. Since then they have recurred and a psychosis has developed

These cases of lues cerebri and lues spinalis represent, after all, a less chronic form of the disease and one in which the morbid process is more likely to be of the exudative kind, the variability of the symptoms being largely due to the changes in exudate and in the vascular affection of the meninges and of the brain and spinal-cord tissue. One case of tabes with epilepsy has been markedly benefited by the treatment, inasmuch as the convulsive seizures, which had been frequent and which were evidently due to active specific involvement of the meninges, had subsided for a number of months, while the tabic symptoms have remained entirely stationary. The most satisfactory results following the treatment have occurred in that smaller group of nine cases of constitutional lues with special nerve symptoms. We refer particularly to the cases of chronic specific headaches with some other nervous manifestations, and it is astonishing that so few cases of this sort have as yet been recorded in the literature of the subject.

We have seen a fellow physician, who had acquired lues a number of years ago, whose blood was strongly positive, and who has received both intravenous and intramuscular injections on four different occasions during the past year. He had been suffering from intense headaches, inability to work with comfort for years, and a total lack of concentration upon his work. He is a man of calm and deliberate judgment, and in his own opinion the drug had done wonders for him. In February, 1911, he recorded a complete recovery from former troublesome symptoms; he was active in practice, and most enthusiastic in his comment on the effects of treatment; speaks of the return of his "old-time energy," his head is perfectly clear. In September, 1911, there was a slight return of his former symptoms, but improvement again followed upon another intramuscular injection. In July he had a squamous eruption, which disappeared after inunction treatment of five days. Similar improvement, particularly of chronic specific headaches, has been observed in other cases, and, if in no other, it is at least in this series of cases that we would give salvarsan preference over all other remedies hitherto employed.

We conclude that salvarsan has no curative effect in tabes and general paresis; that it seems to influence favorably some of the symptoms, particularly the vesical and sexual functions, and that under its use some of the cases remained stationary, and that none of them exhibited any unfavorable symptoms attributable to the drug itself; that in these two diseases it accomplishes as much as, but not any more than, was achieved in former years by the use of mercurials. In brain and spinal-cord syphilis the administration of salvarsan is followed by improvement in many of the symptoms, and it seems to accomplish at least as much as mercury did in these diseases. In the acute and subacute forms of brain syphilis, particularly in those associated with convulsive seizures and with chronic headaches, the drug has exercised a distinctly beneficial influence. There is no doubt, however, that the good effect of this treatment may be made more lasting by the additional use of mercury and the iodides.

In spite of these rather negative impressions, we must not lose sight of the fact that the drug may prove most efficient in the prevention of parasyphilitic and metasyphilitic diseases of the nervous system. That general paresis, and probably tabes, run a more slowly progressive course, and, on the whole, a milder course than they did in former years is true beyond a doubt. It is to be hoped that the administration of salvarsan in the early stages of syphilitic disease may prevent the development of late and more serious forms of specific disease of the central nervous system.

THE UNRECOGNIZED TRAGEDIAN, SYPHILIS.

By E. HARRISON GRIFFIN, M.D.,

NEW YORK.

Away back, when I was in the swaddling clothes of my profession, shortly after receiving my degree, I had the pleasure of being present at a dinner, given in honor of Sir Morell McKenzie. The evening was taken up with a paper on laryngeal phthisis. The paper was followed with a discussion by various members of the nose and throat world of the time.

Sir Morell McKenzie stated that he could diagnose positively an ulceration of the larynx as either tuberculous or syphilitic in about eighty per cent. of the cases, while twenty per cent. were open to question. A very eminent member of the profession stated that he could diagnose positively laryngeal phthisis in every case.

A short time after this I chanced to see a case, which this person had diagnosed as laryngeal phthisis, given a prognosis of certain death in six months or less, and at the next lecture had changed the diagnosis after the case had been treated with the iodides. This little fact taught me to be very careful in a diagnosis of an ulceration when situated in the larynx. Years have passed since that period, and at the present time the more certain I am in regard to a diagnosis of an ulceration situated in the larynx the more careful I am in giving a positive diagnosis.

The following case emphasizes the above: Mrs. X., married, one child, age five years, had never had a miscarriage and had never been ill until she applied for treatment to me four years ago. She

then applied for a bronchial cough, had lost ten pounds in weight, and was troubled with fever and chill. An examination of her lungs was negative. She improved under tonics and remained well until she applied to me again, some months afterward, complaining of a cough and a pain in swallowing. An examination of her lungs showed consolidation at the apices, and her sputum contained a few tubercle bacilli. The examination of her larynx showed a marked edematous swelling of the epiglottis with an edema of the arytenoid cartilages. The membrane was pale in color and had the anemic appearance that is commonly found in laryngeal phthisis. The pain in deglutition, the marked anemic color of the membrane, and the microscopic examination of the sputum left no question in regard to the diagnosis. I saw her brother and gave a grave prognosis. Her condition was such that I did not think any benefit would come from removal to the mountains.

I placed her under creosote and morphine internally for her cough, and gave her throat the usual medication demanded in phthisis of this part. The patient steadily grew worse; there was no doubt in my mind in regard to my diagnosis. One day I thought I would place her under the syphilitic treatment, to give her the benefit of a doubt. Inside of a week the edema began to diminish, the cough lessened, and in three weeks the larynx was healed. Here is a case of a mixed sore. There was absolutely no history of any syphilis, no miscarriages, no eruption, no sore throat, no alopecia—negative, only negative. At this writing her larynx has completely healed and she is gaining in weight.

Some years ago I wrote an article showing the importance of recognizing the mixed sore, especially when situated in the larynx. The above case emphasizes the fact how important it is to recognize that great actor, syphilis.

All the world's a stage and we are merely actors. We've had our McCready, Booth, Charlotte Cushman, Bernhardt, who trod the boards and played their rôles to perfection. Iago, Hamlet, the Romeos and Juliettes have passed before our eyes again and again; these characters have been portrayed so perfectly that at times the actor is lost sight of, and it is not the actor we see, but the Iago or the Hamlet in the flesh and blood. These are produced in some large playhouses; but I know of no playhouse where the bill is changed more often, and the play more perfectly performed, than that acted again and again upon the stage of the human body.

A bursting of a bag of water, a short prelude, and there is brought into the world a stage upon whose boards is played a repertory more varied, more distinct, than in any theater. The abilities of Booth, Barrett, and Cushman sink into insignificance compared to this great artist, who changes his color, his location on the stage of life, and plays his part so well, disguising himself so perfectly that he is seen again and again in various rôles and still unrecognized. I mean that superb actor, Syphilis.

Who cannot recall a case where he has made his appearance on the boards of life when the child is only a week or more old? His makeup has been so perfect, his characteristics so obscured, that the actor is unrecognized, and the spots we see mottling the stage, the great stage of life—the body—is called by any other name but the true one. It is here again and again mistaken for measles, scarlet fever, or some other malady rather than the correct one. These words are not dramatic; these words are not mere play; they are facts, unblemished facts, which I can support by case upon case which I have seen in either consultation or in my clinical work.

The puling infant now grows into childhood, a boy or a girl, we will say, in the teens; here again this artist plays his rôle and again disguises himself so perfectly that he is unrecognized. We find him perching himself upon the tonsil in the shape of an enlargement of the gland; there is no ulceration, there is no mucous patch; there is simply a congestion; but if we raise our curtain a little higher and examine the skin, the mottled appearance and the eruption permit us to see through the maze and to recognize our versatile actor, Syphilis.

The closed-up nose, the pus discharge, and the bleared eye are again accoutrements for this dramatist to play his part. These are more his gowns for hereditary syphilis; but his wardrobe is perfect, more varied when he plays his full repertory from his initial lesion to the old age of necrosis.

John Drew might possibly hide his identity in a dime museum, as the chancre hides its identity when it steps out from the reproductive organs and begins making history in the mouth, or the scalp, or perchance on the wrist as an initial lesion. I have seen this lesion make its début in all localities and play its part as perfectly as if it had started in its home theater, the reproductive organs. A chancre of the tonsil in ninety-nine cases out of a hundred is overlooked. The actor is not called by his stage name of Syphilis, but is called possibly Mr. Mumps, an enlargement of a gland, or some other *nom de plume*. He has played his part now as the chancre for three or more weeks, and, wearying of his tragedy, he calls Dame Nature to his aid and disappears from the scene as perfectly as Harlequin in the pantomime, but only for a moment, when he again comes upon the stage, like Harlequin, in another disguise, and besmears the body with a ruddy eruption that may pass unrecognized, because in this rôle he gives so little trouble. Again that great physician, Dame Nature, steps in and this lurid mottling disappears from sight. He is no longer the amateur; he has trod the boards of the body now for a year or more. His quest for glory is still unsatiated. He wishes to play a more important rôle; he now attacks the mucous membrane. Here he finds his field so fertile that he is able to play a varied repertory. His syphilitic iritis, his mucous patches of the tonsil, his rôle of alopecia, are played to perfection.

Again the curtain descends, an interlude is played by the orchestra, an intermission occurs; but soon the curtain goes up again and we find our artist seeking even deeper ends. He is no longer satisfied with playing the superficial rôle of the mucous patch or of only besmearing himself in a mottled condition on the skin; his aim now is to penetrate deeper into his profession and to engulf not only the superficial layers of that great stage, the body, but to penetrate deeper and still deeper into his artistic career. He now makes his appearance as a gumma, then throwing off his mask and appearing as the deep ulceration, implanting this possibly upon the pharynx or perchance the larynx, or maybe the vault of the pharynx, here shifting his scenery to the bones of the nose, to suit his whim. Now he causes his exfoliations, and if not recognized will so shift and change the anatomy of this part in a few weeks that the part, which was at first swollen, will shrink, fall

in, and the stage will be bereft of all adornments.

His ambition is still unsatisfied. He is still discontented. I know of no actor that is so prolific. He now attacks the arteries of the body, possibly suspending animation in some of its extremities by perching himself upon that throne, the brain. Here he produces his paralysis, his agraphia, and, extending down the cord, his locomotor ataxia.

A repertory of which any Booth or a Barrett might well be proud, but still that mighty actor, Syphilis, is discontented; like Alexander, he wishes for more worlds to conquer. He hesitates, muses, and thinks, but not for long. His versatile, energetic being is untired; he now seeks the main arteries of the body, possibly the arch of the aorta. Here he steps upon a throne from which, when once having taken possession, he rules with a mighty sway. He is no longer an actor, no longer a little, mild, puling infant, the chancre, but the despot that commands attention and usurps the body as any conqueror. He changes the character of the arteries, and with his decaying touch brings forth an aneurysm that may press upon one of the recurrent nerves and give rise to a hoarseness and a cough; or, wishing to vary his monotony, he may branch out and press upon the trachea, causing dyspnea. His rule is unquestioned; he becomes the usurper, he dictates his terms, and now perchance, wearied with his work, like Sampson, he opens up one of these aneurysms of the arch; a quart or more blood is expectorated through the mouth, and this great actor passes from this stage and the tragedy is ended.

Now *mon père Syphilis* is dead. We've had our elder Booth and our younger Booth, we've had our Salvini, who played his Othello and at times, it is said, broke the ribs of his play wife, Desdemona, the younger Salvini, who played the leading man with Clara Morris. We see here the talent of the father descending to the son. Syphilis is no bachelor. *Mon père* is dead, but his offspring has ascended the throne and rules with a mightier sway than even the father. It is dogmatic, tyrannical, and overbearing in its sway. It is not only a member of the anatomy; it is here paramount, supreme, and it takes no second place; it retreats to no back corner, but is all supreme.

Where the father was ushered into the world as a modest chancre, and took years to rise to his supremacy, the offspring has all his powers and virulence; it is like a rich man's son, it has acquired all his wealth, all his power, and starts with its wealth of destruction in its grasp and implants upon its unfortunate possessor manifold destruction. *Mon fils* has acquired all his father's wardrobe and starts out to play his part, not with a question, Do I fill my father's shoes? But I have his accoutrements in my grasp and am more powerful than *mon père* Syphilis ever dreamed to be. He plays his part at birth in the character of an eruption, which eruption is often mistaken for the measles, scarlet fever, or some kindred disease of childhood. In later years he may locate his playhouse in the nose. Here he moves his scenery so often and so ruthlessly that an ulceration appears, the bones are exfoliated, the supports are necrosed, and the nose falls in. Perchance he may alight upon the tibia or the fibula; this he ulcerates and necroses. The bones exfoliate. The glands of the neck he attacks, or else he may sight out the palate. Here he plays a most regal rôle. Nothing seems to hold him in check, except that great angel, the Iodides. Without this check his rule is all supreme. He starts as a small ulceration, and in a short time the stage is cleared, the uvula, the palate and the pharynx have received the marks of his imprint, a most dastardly touch, a gummatous condition, an ulceration and an adhesion, and the human theater is polluted for any other production.

55 West Forty-seventh Street.

SEXUAL NEURASTHENIA AND THE PROSTATE.

By G. FRANK LYDSTON, M.D.,

Chicago.

Professor of Genitourinary Surgery and Syphilology, Medical Department Illinois State University.

For the purposes of this brief article sexual neurasthenia implies ordinary neurasthenia with a sexual element, either psychic or physical in character. Organic sexual disturbance can hardly exist without a strong incidental psychic element. A purely psychic sexual element in so-called sexual neurasthenia is rare. There is almost always some functional derangement of the sexual apparatus behind which lies a varying degree of organic disorder.

My experience leads me to the conclusion that neurasthenia in the male is associated with prostate hyperemia and hyperesthesia of the prostatic urethra more often than with any other condition.

Knowing the abundant sensory and sympathetic nerve supply of the prostate and its intimate relation to the sympathetic system in general, one should not be surprised at the frequency with which nervous symptoms develop in patients suffering from prostatic disease. Add to the purely organic factors the profound psychic impression made upon the patient by the knowledge of sexual disability and we have a very satisfactory explanation of the frequency of "sexual neurasthenia."

Disturbed digestion, irregular bowel action, headache, depression, lassitude, melancholy and brooding, hypochondriasis and introspection, unstable emotions, and "hysteria"—for there is a condition in the male analogous to hysteria, which we logically might call "prostateria"—are among the results of a sensitive, congested prostate and deep urethra.

It is the custom of the reputable profession to regard the sexual neurasthenics who are the prey of the quacks as sufferers from purely imaginative ailments. As practically all of these subjects have been masturbators, many of them have indulged in sexual excesses, and not a few have had gonorrhea, the verdict of the profession is not always sound as regards the quack's victim, however just it may be as to the quack himself.

Reputable medical men are wont to wave the sexual neurasthenic away with a bluff and hearty "My good friend, forget it. There is nothing the matter with you." The patient seeks for some one who will sympathize with him, and goes to the quack. The quack doesn't find out what the matter is but, to the patient's cost, he does find a lot of things that do not exist, and all because the reputable physician flouted as imaginary conditions which, to the patient's sensitive and morbid mind, are always terribly real. The layman who feels, however erroneously, that the regular profession is both ignorant and unsympathetic is fine food for the quacks.

I doubt if it is possible for one to indulge in either masturbation or sexual excess for any great

length of time without producing disturbance of prostatic circulation and innervation. We advise such patients to stop their evil habits, but ignore the sensitive prostate and hyperesthetic veru montanum which are continually sending sexual stimuli to the psychosexual centers, where they are at once transformed into erotic ideas. These erotic pictures of the imagination reverse the nerve current, so to speak, and increase the prostatic irritation. The patient's sexual emotions are used as a shuttlecock by the seat of sexual sensibility in the prostate on the one hand and the psychosexual centers on the other.

We tell such patients to keep their minds off their sexual organs; this is a pseudo-Christian Science prescription which works satisfactorily only when conjoined with the instillation of a little nitrate of silver solution into the prostatic urethra supplemented by prostatic massage.

Practically every masturbator who has practised the habit for any length of time may be considered as having a more or less tender and swollen prostate. My experience goes to show that this condition underlies many of the cases of nocturnal emissions with which we meet.

The analogy between the prostate and seminal vesicles and the uterus and tubes is nowhere better shown than by pathological conditions of these organs. The infected subinvoluted uterus and tubes, with the surrounding pelvic infiltration producing pressure symptoms and neurasthenia, have their counterpart in the enlarged infected prostate, infected seminal vesicles, and periprostatic infiltration, producing the same local disturbance and general nervous symptoms. The two conditions are alike in the matter of the stubbornness and lasting quality of the infection.

The management of sexual neurasthenia, while largely directed to the relief of local conditions, requires even more care and judgment than that of cases of neurasthenia in which there is no sexual element. Regulation of sleep, diet, and work is always in order. Hydrotherapy, general massage, and static electricity all have their uses, in conjunction with prostatic massage, instillations of silver, and, in infected cases, irrigations. Urethral dilations should supplement the other local treatment.

We occasionally meet with cases in which, while the local conditions improve and the neurasthenia is more or less benefited, the patient remains unfit for the active duties of life and becomes a confirmed hypochondriac. For cases such as these complete change of scene and climate is required. A sea voyage sometimes accomplishes wonders. In a series of cases of my own in which a sea voyage was practicable the results were all that could be desired. I recall one case of a gentleman whose will was so unstable that it was necessary to keep some one with him constantly until the steamer started, lest he should fail in his determination to take the voyage. He was so emotional that, when his frequent fits of self-pity came over him, he would cry like a child. This meant much in a man like him, for he was an ex-soldier of tried mettle and courage. He first went to the Philippines, then to Japan. He returned perfectly well in five or six months, as he expressed it, snapping his fingers at the doctors. This case is but a type of a number in my experience.

Sexual neurasthenia associated with real or imaginary spermatorrhea, obstinate prostatorrhea, or seminal emissions occurring frequently and resistant to treatment is sometimes very difficult of management. In such cases I have frequently obtained excellent results from temporary resection of the vasa deferentia. Aside from the moral effect, which is profound, the relative rest secured for the sexual apparatus and the lessened activity of the circulation of the prostate are extremely beneficial. As I have elsewhere shown,* and have demonstrated in my own work, subsequent anastomosis is perfectly practicable, by my method of coupling the vas on silkworm gut.

Cases of sexual neurasthenia with or without prostatic derangement associated with impotency are the most trying of all. If unrelieved, these cases go from one doctor to another and finally land in the arms of the quacks. Many of them are purely psychic at the beginning, but a few recurrences of their inability to copulate puts a large proportion of them into the permanent class. In such cases the nomenclature "psychic" is not comforting to the patient, and if one stops to think is somewhat absurd. One of my patients rather rudely brought me to a realization of the profession's lack of humor. When I told him that his impotency was purely psychic, he replied: "Psychic h—l! Why, I can't get an erection."

As potency really consists of ability to get and sustain an erection, my patient's point was well taken. I would remark, in passing, that our nomenclature has driven a host of patients to the quacks. The cause of impotency may be psychic, but the lack of erective power *per se* is a purely mechanical proposition.

In many cases of impotency the failure of erective power is due to plainly evident general or local organic conditions. Once the accident of failure of erection has occurred, however, the patient's memory of the first failure is sufficient to cause another and another, until failure is the rule of his sexual life. Here even the removal of the original organic condition is likely to fail to cure.

Morbid prostatic conditions, involving especially the veru montanum, often underlie impotence. In such cases message, silver instillations, or endoscopic applications of silver to the veru montanum often do excellent work. Not infrequently, however, all these measures fail completely. Unless the impotency is relieved, cure of the neurasthenia is impossible, hence any measure that holds out hope of relief should be adopted. It has been my experience that a very respectable proportion of cases of sexual neurasthenia associated with impotency are remediable by resection of the vena dorsalis penis. As to how far the psychic effect of the operation explains its benefits I am unable to say, but as the local mechanical effects are obvious and constitute the only means of psychically impressing the patient I will not quarrel with terms. The patient, noticing an immediate increase in the functional activity of the penis, is justified in having some psychic impressions from the operation, and, as these impressions run counter to those which have been a prominent feature of his sexual disability, the operation would seem logical enough. Even a small proportion of cures would justify the operation, and, as the proportion is really large, I believe that the procedure should be generally employed in suitable cases. It is hardly necessary to say that proper surgical technique is essential. In a large proportion of cases that have been submitted to the

Journal American Medical Association, Vol. XVIII, No. III.

operation the cutaneous vein has been resected and the failure charged up to the operation. It should be unnecessary to say that the dorsal vein and the dorsal cutaneous vein are not the same.

BLOOD PRESSURE AND THE PATIENT.

By WM. HILLS SHELDON, M.D.,

NEW YORK.

INSTRUCTOR IN MEDICINE AND CHIEF OF CLINIC, OUT-PATIENT DEPARTMENT, CORNELL UNIVERSITY MEDICAL COLLEGE.

Since I have been interested in the study of blood pressure I have been surprised, not so much at the frequent occurrence of the condition as at the information of patients concerning this condition. Every practising physician knows that medical knowledge can be assimilated by the lay mind only in homeopathic doses, and my experience has shown me that the present popularity of blood pressure is causing serious mental indigestion among those who fail to understand its significance.

A few years ago patients endeavored to assist a physician in his diagnosis by informing him, "Doctor, I am full of uric acid." A few years later it was "Doctor, my hemoglobin is low." Following that came the statement, "My free hydrochloric acid is 5/10 per cent." At present it is, "Doctor, I have high blood pressure." Now, the uric acid theory was harmless, low hemoglobin not necessarily fatal, and the percentage of free hydrochloric easily remedied. But blood pressure is an altogether different matter.

In a large number of elderly persons a heightened blood pressure seems as inevitable as white hair. As it is absolutely incurable in advanced cases, and very probably a compensatory phenomenon, it is highly desirable, in the majority of instances, that the patient should be kept in ignorance of the fact that his tension is high. I refer particularly to that class of highly organized, nervous individuals who seem to be specially liable to this condition.

A number of cases have recently come to my notice which illustrate the imprudence of telling patients about their blood pressure. A physician came to my office one day and said, in an agitated voice, "Doctor, take my blood pressure." I saw he was greatly upset. Upon inquiry I found that he had felt perfectly well till two weeks previous, when a medical friend had told him that his blood pressure was high. Since that time his wife had taken his blood pressure night and morning, and his attention was absolutely riveted on the matter. I talked to him on various subjects for some time, and then took his blood pressure. I found it 160 mm. As an experiment I told him it was high, and took it again. In the few minutes that had elapsed it had jumped 20 mm. I then explained what I had done, and was able to demonstrate to him how worry heightened his tension.

A certain manufacturer was told by his physician that his blood pressure was high, and the dangers of this condition were considerably exaggerated. For several months this patient, a very nervous man, had his blood pressure taken several times a week. After taking certain pills his physician would tell him that it was lower, and when they were withdrawn that it was higher. When his blood pressure rose he would worry over his condition to such a degree that he was unable to sleep. Insomnia and constant fretting soon affected his general health, and his friends noticed that he looked older and thinner, and, as is the habit of friends, told him so. On these occasions he would transfer his attention from his blood pressure to his tombstone. Finally he went to another doctor, who explained to him that blood pressure was a symptom and not a disease, and outlined a sensible but not too severe régime. Under this treatment the patient has regained in health, weight, and mental composure what he had lost by the unfortunate and quite unnecessary revelation of his high tension, and it is only at long intervals that his blood pressure is now taken.

This is one of the innumerable instances which show how little study some physicians give to the psychology of their patients, and it is greatly to be regretted that more attention is not paid to this most important factor in the successful treatment of disease.

I know of one patient with postretinal hemorrhages who fell into the hands of a blood-pressure-electrical enthusiast. Three times a week he took her blood pressure and gave her electrical treatment. This lasted until her money gave out. She then went to an oculist, who had once treated her. He found her almost totally blind and in wretched physical condition.

I am inclined to believe that the less the average patient knows about his blood pressure the longer he will live and the happier he will die. There are, of course, a certain number of cases in which the only method of controlling vicious habits is by exaggerating the danger of this condition, but these are in the minority. The majority of cases are merely aggravated by such knowledge. For once a patient is told he has a high blood pressure there is no way of protecting him from the misinformation of his friends, those kind, well-meaning friends who add so greatly to the problems of the physician. Once a man's attention is fixed upon his blood pressure it is almost impossible to pry it loose. There is always the danger also that a patient may obtain some of the literature on this subject, the tone of which is distinctly pessimistic.

With regard to the present outlook of blood-pressure conditions, it is as well to remember that not many years ago cases of mitral regurgitation were regarded as giving a very serious prognosis. But now our attitude toward these cases is entirely changed. Blood pressure is a relatively new subject and can bear considerable investigation. It will be many years before we have an accurate appreciation of its value as a symptom, and, in the light of medical history, it will doubtless be as well not to overestimate its dangers or the seriousness of its prognosis.

As I have said in a previous article, the importance of blood-pressure determinations lies in their being taken early in life, before the condition has become chronic and when it is most amenable to treatment. If this were done as a routine method its serious effects later in life could be avoided. But in long-continued cases it is incurable. All that can be done is to keep the patient comfortable, and this cannot be accomplished by telling him that he has a high blood pressure.

New York, February 3, 1912.

THE NATIONAL CONTROL OF NEW YORK QUARANTINE.

THE anomalous situation with reference to the administration of the quarantine of New York harbor has reached its climax of absurdity. The spectacle no less tragic than grotesque of the executive of the Empire State looking about for some one competent or willing to take the place of Dr. Doty, who with meager facilities has sturdily guarded the sanitary gateway of the Western World, can admit of but one interpretation. The State of New York can no longer be trusted by the nation to supervise the quarantine of its principal port. If there has ever been need for argument why the quarantine of any port should not be under Federal control, surely that need has vanished in the face of the object-lesson that has been lately unfolded. With the health officer of the port facing the insidious bearers of pestilence from abroad, and at the same time being compelled to defend his administration from the attacks of his political foes at home, it was an act of Providence that cholera did not gain a foothold in this country during the past summer. It should be a source of pride to Dr. Doty that during his incumbency of office the national government has never questioned his ability to defend the entire country from pestilential invasion.

But the quarantine of any port should not be left to the chance appointment of any man who may or may not be capable. The quarantine administration of the entire country should be systematized and uniform, with a machinery and a personnel perfected with the precision characteristic of the standing army or diplomatic corps. That machinery and that personnel exist to-day in the splendid organization of the Public Health and Marine-Hospital Service, which is acknowledged even by foreign authorities to be unequaled by any similar organization in any other part of the world.

In the current issue of the *Survey* the editor makes a plea for the national control of the quarantine of New York harbor. This quarantine should be purged of political interference, should be uniform and standardized, adequate in its hospital and laboratory equipment, and capable of reconciling the interests of passengers and commerce with those of safeguarding the public health. In only three cities, Boston, Baltimore, and New York, is quarantine still under the obsolete system of State control, while in forty-four other ports the national government exercises this supervision. Yet the most important port of the entire country, New York, through which pass in one year eight hundred thousand persons or three-fourths of the immigrants coming to this country, is left in the sanitary control of the local authorities. A large proportion of these immigrants are destined for parts of the country more or less remote from the port of entry. Why should the expense, the burden, the responsibility, and the danger of merely local supervision be tolerated in the most important gateway of the country, while the national government exercises this control in all the minor ports? Surely there is a precedent for the extension of this control to New York, for in 1892, when the cholera menace became most acute, the national government stepped in and took charge of the quarantine administration of New York harbor.

The safeguarding of the country from epidemic invasion from abroad is not a local function; it is national, if not international, in its scope. There should be a perfect coordination of activities throughout the country, with the assistance of the foreign agents of the public health authorities; with the utilization of all the sources of information, and the adoption of the most modern methods of quarantine supervision. This is possible only under Federal control. A movement with this end in view was inaugurated at a meeting of the Academy of Medicine on Thursday of this week (see page 226) when papers showing the advantages of the national control of quarantine were read by Assistant Surgeon-General L. E. Cofer of the U. S. Public Health and Marine-Hospital Service and Mr. William Williams, Commissioner of Immigration at the Port of New York. But one of the strongest arguments in support of such a move has been unwittingly furnished by Governor Dix.

CHRISTIAN SCIENCE IN THE CANAL ZONE.

IN the issue of the MEDICAL RECORD of January 27 attention is called by a correspondent to the startling fact that the Christian Science healer has received a special dispensation from the Canal Zone administration to practise his sanctimonious calling. Dr. Baruch had commented on the singular fact that in the Zone, where the United States Government has achieved the greatest sanitary triumph of modern times solely through the efforts and sacrifice of medical men, it discriminates against the latter by placing the science healer on an equality with the physician who has expended years of study and effort to master his profession and from whom it demands an examination and license. The Secretary of War made an absurd defense of his anomalous position and now comes an anonymous, probably inspired, writer in the *Sun* of January 27, who claims that, in addition to the States (Connecticut, Maine, New Hampshire, South Dakota, and Tennessee) enumerated by our correspondent as exempting these healers from the license required by medical men, there are Illinois, Kansas, Louisiana, Utah, Massachusetts, and probably Vermont and

Washington which have legislation similar in purpose. It is surely admitted, he writes, "that this is an imposing array." Not at all.

We have taken pains to investigate this addition which is claimed to form the "imposing array," with the following result: Massachusetts does exempt from license and examination "registered pharmacists prescribing gratuitously, osteopaths, clairvoyants or persons practising hypnotism, magnetic healing, mind cure, massage, Christian Science, or cosmopathic method of healing," provided, however, they do not violate the provisions of Section 8, which reads: "Whoever not being lawfully authorized to practise medicine holds himself out as a practitioner of medicine . . . shall for each offence be punished," etc. Illinois provides that "the examination of those who desire to practise any other system or science of treating human ailments, who do not use medicines internally or externally, shall be of a character sufficiently strict to test their qualifications as practitioners." In Vermont, after providing that all practitioners of medicine shall be examined and licensed, the law says: "The provisions of this act shall apply to persons professing or attempting to cure disease by means of faith-cure, mind healing, or laying on of hands, but shall not apply to persons who merely practise the tenets of their church." In Utah, after providing that all practitioners be examined and licensed, the law says: "This act does not apply to those who heal only by spiritual means without pretending to have knowledge of the science of medicine." In Louisiana, after carefully providing that all practitioners are examined and licensed, the law says: "Nothing in this act shall be construed to prohibit the practice of religious tenets of any church whatsoever." In Kansas all physicians must be licensed as in other States, but "the act does not apply to domestic medicine or gratuitous service." In the State of Washington all persons practising medicine must be licensed and no exception is made for any reason whatever. It has remained therefore for the Canal Zone administration, not to "follow the legislation of a large and important number of States" (the imposing array numbers seven), but actually to lead them all by permitting the practice of the religious tenets of any church in the ministration to the sick or suffering by mental or spiritual means, whether gratuitously *or for compensation*. This clause is found in the laws of no other State in the Union. Of what use is it for any one to spend years in preparation for the study of medicine, then pass six years in study and hospital work, if one may adopt the more simple and direct way to become a healer, practise medicine without let or hindrance, and escape State examination?

Dr. Baruch's suggestion that the medical profession take immediate and effective action to meet these disgraceful encroachments on its rights and privileges is worthy of serious consideration. It would seem on calm consideration of all the data that medical men are actually legislated against by several States in order to protect the special interests of clairvoyants, magnetic healers, Christian Science healers, *et id genus omne*. The situation demands investigation by competent legal authority to determine whether our rights as citizens are not discriminated against by the laws of these seven States, and whether there should not be a resort to legal steps to secure these rights.

THE WHOLESALE POISONING EPISODE IN BERLIN.

Somewhere about January 20 a cablegram in the local daily press announced that the mysterious wholesale poisoning in Berlin had been found to be nothing more or less than methylism, and that the joke (if joke there could be in such a tragic happening) was on the doctors. It was evident, however, that the symptoms bore little or no resemblance to the typical effects of wood alcohol, and a letter from P. Fraenkel, who seems to have been in close touch with the autopsies made, and whose communication appears in the *Berliner klinische Wochenschrift* of January 8, makes it evident that this substance must have played a very minor rôle in the endemic or epidemic, for which a number of factors could have been operative. The author saw over sixty of the cadavers and witnessed a majority of the twenty-seven autopsies. The number of alcoholics was singularly small considering the external circumstances of the victims. Contrary to reports in the daily press, most of the supposed outcasts were well nourished. The chief finds were as follows: fluidity of the blood was constant; there were marked reddening of the skin and visible mucosæ and injection of the conjunctivæ, which may have represented a stasis due to exposure to the cold weather; there was also notable hyperemia within the cranium and thorax, while the abdominal organs were correspondingly ischemic; there was intense inflammation of the trachea and bronchi, and also of the intestinal mucosa; finally there was retention of urine. These finds seem to throw little light on the nature of the intoxication. There was at times an aromatic odor to the stomach contents or urine. The character of the lesions in the alimentary tract bore at times some resemblance to the finds in sausage poisoning and methylism, but other evidences in this direction were absent. The intense bronchial irritation suggests the results of the elimination of a volatile irritant poisoning, such as carbolic acid or lysol.

The first suspicion was that involving a contagious disease. Next in order came a possible verdigris poisoning. Sausages were next accused and then wood alcohol. All these factors seem to have been excluded, as has, of course, the theory that death occurred from a cumulation of all factors which make for starvation and misery. That the mystery is not yet solved is not strange. Not sufficient time has elapsed for full chemical analyses and histological studies. Furthermore, it is not always possible to solve problems of this character from autopsy findings alone, and the complete history of the supposed epidemic still has to be ascertained. Similar episodes, less severe in character, may, and very probably have, occurred before. Accounts are not lacking of a severe type of gastroenteritis which attacks harvesters by the wholesale in the summer or autumn, and which has, perhaps erroneously, been ascribed to a plant cause. In the words of an eyewitness, these peasants would have been called vic-

tims of the most severe form of influenzal pandemic with gastric location, had not the season been the wrong one for that affection. The disease has never been explained, and is practically a new malady. Possibly it is related to, or identical with, that which slew the Berlin outcasts at Christmas time.

ENURESIS NOCTURNA AND SPINA BIFIDA OCCULTA.

ENURESIS NOCTURNA is commonly believed to be an evidence of a neuropathic degenerative substratum in children. It has been brought into a special association with hysteria, and also with the so-called spasmophilic diathesis. Many years ago it was also brought into necessary relationship with so-called myelodysplasia or spina bifida occulta, but objection was at once made that the two conditions are prone to develop in the same kind of children, and that the defective development of the cord was not in itself the cause of enuresis. In the *Deutsche medizinische Wochenschrift* for July 6, 1911, Peritz writes at much length on this subject and reports a case in which a wide fissure in the sacrum readily appears in a radiogram. He examined two series of subjects with bed wetting, one composed of children and the other of young adults. It by no means follows that the bed must be wet often, for three or four passages a year which cannot be readily explained would constitute a case of enuresis. The author's conclusions are as follows: In every case of bed wetting we must bear in mind the possibility of myelodysplasia. If the later can be diagnosticated, a mechanical plan of treatment is indicated, either epidural injections of saline infusion, which tend to remove the pressure caused by cicatricial tissue, or suspending the patient for a time by the legs, which has a similar effect. Both procedures have to be repeated a number of times, and if benefit does not accrue a plastic operation will be indicated.

In this connection it is of interest to note that H. B. Sheffield of this city has reported a case of the same type in a recent number of the MEDICAL RECORD. The patient, a boy aged seven years, had been treated medically and without success for enuresis diurna and nocturna persisting since birth. By the merest accident a small prominence was remarked in the sacrolumbar region as the boy bent over a chamber vessel to urinate. When he stood up the prominence was effaced. A hiatus in the sacrum was evident without an *x*-ray examination. Peritz's paper had not yet been published, but Sheffield came independently to the conclusion that in obstinate enuresis we should always examine for occult spina bifida. The latter at once becomes so obvious as soon as we are aware of its existence that its overlooking seems singular. Sheffield's patient had a peculiar gait, and in addition to incontinence there was a difficulty in expelling residual urine. A plastic operation was refused by the parents.

SWAMP FEVER IN HORSES.

FOR some years past a peculiar disease of horses, widely known under the name of swamp fever, has engaged the attention of veterinarians and horse owners of various sections of the Northwest. In Dakota, also, the disease has occasioned a considerable amount of damage, and in order to obtain some definite knowledge on the subject L. Van Es, E. D. Harris, and A. F. Shalk were entrusted with the task of systematically investigating the disease. They appear to have done this thoroughly and Bulletin 94 of the North Dakota Agricultural Experiment Station gives an exhaustive account of their findings. Among the conclusions at which they have arrived, the most essential are that swamp fever is an infectious disease transmissible by subcutaneous and intravenous injection and also by ingestion. While not denying the possible transmission of the disease to healthy animals by means of insects and parasites, the author says that animals contract the disease naturally by the ingestion of food and water contaminated by the urine of an infected horse. The blood of an animal may remain virulent for as long as thirty-five months after the initial infection without the infected horse manifesting any clinical evidence of the fact. Such "carriers" probably play an important part in the establishment of more or less permanent centers of infection. Both trypan-blue and atoxyl are worthless in the treatment of the disease. Finally, in the light of present knowledge of the disease, such prophylactic measures must be depended upon as the destruction of diseased animals, segregation of suspects, care in introducing new horses into the stable, and the safeguarding of food and water supply from urine contamination.

MALARIA IN PANAMA.

AT a meeting of the Los Angeles County Medical Association, held October 20, Walter V. Brem presented a review of the prophylactic measures against malaria carried out in the Canal Zone, and discussed the subject of malaria in general (*Southern California Practitioner*, December, 1911). He pointed out that the multiple subdivisions of pernicious malarial fever were confusing, unnecessary, and often based upon misconceptions. As an illustration he reviewed the experience in Panama relative to the "dysenteric type" of pernicious malaria, and showed that such a type does not occur there, the apparently synchronous infections with the malarial parasites and *Bacillus dysenteriæ*, being due to the lighting up of latent malarial infections by the dysentery. According to Brem, all pernicious malarial infections can be classified in one of the four following groups: the group of intense infection, the comatose group, the intermediate hemoglobinuric group, and the erythrocytic hemoglobinuric group. The author endeavored to show by means of experiments that erythrocytic hemoglobinuric fever is a manifestation of malaria. These experiments tended to reconcile the views of those who hold that blackwater fever is essentially malaria and those who contend that it is due to quinine. The treatment of this disease by transfusion of normal blood, in the opinion of Brem, seems to be indicated. In the discussion that followed, A. H. Zeiler, who had worked with Brem in the Canal Zone, said he thought that hemoglobinuria, where the peripheral infection was 6 per cent. or over, was quite common, in fact occurred in nearly all cases. Such hemoglobinuria was usually not of the intensity of so-called blackwater fever. In the Canal Zone there has been plentiful experience of malaria in all its manifestations, and Brem and his coadjutors had under their observation at one time and another no fewer than 4,691 patients suffering from malaria.

News of the Week.

More Yellow Fever on the "Yorktown."—A report from Dr. Parker of the United States Marine-Hospital Service, stationed at Guayaquil, states that he has ten more of the crew of the gunboat *Yorktown* under his care in Guayaquil. Seven of these have yellow fever and three others are suspected of having the disease. Two deaths have occurred.

Cholera in Albania.—A special cable despatch to the *Sun* announces that there are 29 cases of cholera in the city of Janina.

Typhoid Fever in Milwaukee.—An investigation by the committee of the Milwaukee County Medical Society shows that there has been a great increase in the number of typhoid fever cases in that city. There are about forty cases of the disease being treated in the hospitals and inquiry among physicians revealed the fact that there are a number of cases of typhoid fever being treated in their homes and that intestinal disturbances are quite prevalent. The committee urges that the public be advised to boil all water and milk used for drinking purposes.

Meningitis in the Southwest.—Cerebrospinal meningitis, which has been epidemic in Dalls, Waco, Fort Worth, and several other localities in Texas and has appeared in the sounthern part of Oklahoma, is reported to have spread to six counties of that State. A number of fatalities have been reported. Several cases and one death have also been reported from Springfield, Mo. The situation in Texas seems to be well in hand, only a few new cases having been reported since January 15. The United States Marine-Hospital Service has sent hospital tents to the Board of Health of Shreveport, La., to be used in the detention camp that has been established there for persons coming from the infected districts of Texas, and Dr. Dowling, President of the Louisiana State Board of Health, has sent the State health car so that it may be in readiness for any outbreak of the disease that may occur. Dr. R. H. von Ezdorf of the United States Public Health and Marine-Hospital Service has gone to Dallas, Tex., to cooperate with the State Department of Health in combating the epidemic.

Rabies in the Neighborhood of New York.—The town of Westbery, L. I., is under quarantine, conducted by the State Department of Agriculture, on account of an epidemic of rabies. The infection has invaded the stables of the wealthy residents and three valuable horses, one of which was worth $4,000, have been shot within two weeks. A slight epidemic of rabies is reported from Staten Island. Dr. Lederle has announced that he will adopt a new policy in the near future, requiring all dogs to wear muzzles and to be leashed when at large. In New Jersey also many mad dogs have been killed, some after having bitten a number of children.

Pneumonic Plague.—This disease killed 50,000 persons in Manchuria and northern China last year. An interesting report regarding it has just appeared; it is written by Dr. Richard Strong of the Philippine Bureau of Science, and is issued from the Bureau of Printing.

Antityphoid Vaccination of a Hospital Staff.—The staff of the Episcopal Hospital of Philadelphia, doctors, nurses, orderlies, and attendants, have voluntarily submitted to inoculation with antityphoid serum. This is the first time in America that a hospital staff has followed the example of the Army and Navy in the matter of antityphoid vaccination.

Medical Library for San Francisco.—Plans of the trustees of Stanford University have been matured for the new Lane Library building now in the course of construction in San Francisco opposite the Cooper Medical College. The library will be the seventh in size of its kind in America. the building covers an area of 60 by 100 feet and the stacks will be four stories in height, constructed entirely of steel with glass floors, and will have a capacity of 80,000 volumes. There is also a capacity for placing 30,000 volumes on the second floor of the building.

For a National Health Department.—The Republican Club of New York City recently adopted a resolution: "That a national health service be organized which shall coordinate all the bureaus of the national Government now dealing directly or indirectly with the public health, except the medical service of the Army and Navy. That the Federal Government shall take charge of quarantine service in every part of the United States. That action on the foregoing matters be urged upon Congress as of immediate and pressing importance. That this health service shall be organized under the Department of Commerce and Labor, in the title of which the word 'health' shall be incorporated."

The New Charity Directory.—The Charity Organization Society has issued its twenty-ninth annual e lition of the New York Charities' Directory. This publication lists 254 hospitals, dispensaries, and homes for incurables, and 90 asylums for children in the five boroughs of the Greater City of New York. More than 3,000 charitable, philanthropic, and religious agencies in the city are briefly described.

Results of a Practical Milk Test.—At a meeting before a committee of women's organizations, held at the Hotel Astor on January 26, Dr. William H. Park described the results of an observation conducted by the Rockefeller Institute for Medical Research of the comparative health of 500 babies fed on five different qualities of milk. There were 100 babies on each of the following diets: Mother's milk, pasteurized milk, certified milk, ordinary dairy milk, and that obtained from grocers. The superiority of mother's milk was proved beyond question. The results from pasteurized milk were better than from certified milk. The danger from the ordinary milk and the poorer quality was distinctly shown in that seven deaths resulted during the summer months among the babies using this diet, while there was only one death in each of the other classes.

Health Day for New Hampshire.—At the request of the Women's Christian Temperance Union, Governor Bass has designated February 3 as Health Day for the State of New Hampshire. It is stated that the object of setting apart this day is to interest every individual in the community in improved sanitary and hygienic conditions and to emphasize right methods of living whereby the health of the community may be permanently improved.

Tammany Aldermen Are Antivaccinationists.—At a recent meeting of the Board of Aldermen the finance committee recommended that $10,000 in special revenue bonds be issued to pay for the employment of special medical officers to vaccinate

children in the public schools and tenements of New York. Aldermen Dowling, the Tammany leader, opposed the resolution on the ground that he considered vaccination a fad and did not think the "doctors had any right to invade the homes of the poor and scratch the arms of the kids." The other Tammany men voted with Alderman Dowling with the result that the appropriation was refused.

Health and Education Departments Clash on Vaccination Question.—The local Board of Health of Olean, N. Y., has forbidden children who have not been vaccinated from attending school, while the Board of Education of that town disapproves of vaccination and has told the children that they may return to school. As a result of this action 1,400 children are exposed to smallpox, which is prevalent in that section. The local board of health has decided to waive its orders, under protest, until the conflict in the law is cleared up by the Legislature.

To Abolish Public Drinking Cups, Brushes, Combs, and Towels.—The Missouri State Board of Health has passed resolutions prohibiting the common drinking cup, comb and brush, and towel in public buildings, railroad stations, and trains after March 1. Representatives of a number of railroads who were present at the meeting declared themselves in favor of the resolutions and signified their intention of complying with them. Missouri is the twenty-fifth State in which the common drinking cup has been abolished during the past year.

The Smallpox Inquiry in Pennsylvania.—In accordance with a bill passed by the last Legislature of the State ordering an inquiry into the value of vaccination as a preventive of smallpox, Governor Tener has appointed the following men to constitute the Pennsylvania State Vaccination Commission: Drs. J. Frank Schamberg and William M. Welch of Philadelphia; Porter F. Cope, secretary of the Antivaccination League of America and of the Antivaccination League of Pennsylvania; John Pitcairn, another prominent antivaccinationist; and three jurists, ex-Governor Samuel W. Pennypacker, George Wharton Pepper, and Emil Rosenberger.

Dr. F. B. Fusion of Springfield has been elected president of the Missouri State Board of Health.

Dr. Charles A. Bundsen of South Downing, Col., has been knighted in the Order of Vasa by King Gustaf of Sweden in recognition of his work in connection with the establishment of the Swedish National Consumptives' Sanatorium in Denver. Dr. Bundsen was awarded a medal for bravery by the United States Government and the State of Colorado at the close of the Spanish-American War for his services in the Philippines.

Dr. J. Clark Hubbard of Holyoke, Mass., has been elected president of the Williams College Alumni Association.

Dr. Harvey W. Wiley was the guest of honor of the University Club of Brooklyn on the evening of January 21, which was "Doctors' Evening." Among the other speakers were Dr. William M. Polk, Dr. Eugene H. Porter, Dr. Edward E. Hicks, Dr. E. H. Bartley, and Dr. Zachary T. Emry.

In Memory of Pasteur.—John D. Rockefeller has given $11,000 toward the preservation of the house in which Pasteur was born. The house is located in the village of Dôle and the villagers have offered to give their aid in making repairs without charge.

Health Board Bars Wood Alcohol. At a meeting of the New York Board of Health on January 23 a new section to the Sanitary Code was adopted which prohibits the sale or use of wood alcohol in any food or drink or in any preparation or mixture intended for internal or external use by man. This section was directed not only against the use of wood alcohol in food or drink, but also against its use by barbers and others in hair tonics, face lotions, and other external applications.

Hospital Heads Plan Social Service Work.—Plans for a permanent conference on hospital social service were completed at a meeting of hospital officials and social workers held at the New York Academy of Medicine on January 24. The object of the conference is to stimulate the growth of social work departments in all the hospitals of New York City and to standardize the work of these departments when they have been established. Delegates from other organizations in the city desiring to assist in the work will be welcomed. Dr. John Winters Brannan, president of Bellevue and the Allied Hospitals, was elected permanent chairman of the conference.

Phipps Institute for the Study, Prevention, and Treatment of Tuberculosis.—Official record has been made in the city of Philadelphia of the transfer of the new hospital built and endowed by Henry Phipps of Pittsburgh to the University of Pennsylvania. The cost of the new building is $300,000, and the entire project will represent an outlay of about $1,000,000.

Philadelphia Medical Club.—At the annual meeting held January 19 the following officers were elected for the ensuing year: *President*, Dr. S. Lewis Ziegler; *First Vice-President*, Dr. B. Alexander Randall; *Second Vice-President*, Dr. Wilmer Krusen; *Treasurer*, Dr. Lewis H. Adler, Jr.; *Governor*, Dr. E. E. Montgomery; *Directors for One Year*, Drs. McCluney Radcliffe, Chas. A. E. Codman, Wm. Edgar Darnell, John W. West, and Wm. Duffield Robinson.

William McKinley Hospital Seals.—The William McKinley Memorial Hospital League, which plans to raise $7,000,000, half of which will be used for the erection of a memorial hospital in New York and half for a national crusade against tuberculosis, put its seals on sale on January 29, which was the anniversary of the birth of William McKinley. The stamps sell for a cent apiece and are to be used after the fashion of the Red Cross seals.

The Stonywold Sanatorium Corporation held its eleventh annual meeting at the Hotel Manhattan, New York City, on January 25. Its annual report was unlike that of most institutions in that its running expenses were $4,000 less during the year 1911 than for 1910. This saving has been effected by careful economy in all departments.

National Control of Quarantine.—The meeting of the Academy of Medicine on Thursday of this week was devoted to a discussion of the advantages of the federal control of the quarantine service at all the ports of the country. Dr. L. E. Cofer of the United States Public Health and Marine-Hospital Service read a paper in which he stated these advantages as follows: (1) Uniformity of quarantine regulations and quarantine procedure. It is of distinct advantage year in and year out, for both the commercial and sanitary interests, for the quarantine functions to be operated by one corps of officers under one set of laws and regulations. The

tendency under these conditions is to have every one affected by quarantine laws, that is the quarantine officers, the municipal or local health authorities, and the mercantile marine interests, develop among themselves team work along the lines under consideration. It means a great deal to the maritime interests to be familiar with what is required of them, and to know that once they are familiar with the quarantine operations in one port they are familiar with them in all ports, and it is of great advantage to the quarantine officers to know that the mercantile interests understand the code under which quarantine is administered. (2) The Treasury Department by correlating the work of its Customs Division and Revenue Cutter Service Division with the Quarantine is able to furnish the latter with the maximum amount of assistance and dispatch. (3) The national quarantine establishment is in direct touch with all parts of the world through the State Department and its consular bureau, and publishes a weekly bulletin devoted to sanitary reports and statistics. While the State quarantine officers have access to these bulletins, they cannot possibly be in such close touch with the sanitary conditions of the world as can the officers of the Public Health and Marine-Hospital Service. (4) The quarantine officers in the national service are appointed for life, consider themselves residents of no place in particular, and are non-partisan in the performance of their official duties. Their time and their mental activities are devoted to their work and they are not disconcerted by fear of removal from office. Their acquired knowledge of marine architecture, nautical usage, and maritime conditions enables them to adjust in perhaps a judicial way the many differences of opinion and difficulties which arise in the enforcement of quarantine laws upon maritime commerce. It has been the endeavor of the service to create a genus which may be termed a "quarantine officer," which, in the broad sense, would designate a well-appointed medical man, versed in maritime conditions and usage and gifted with executive ability and tact. Fortunately the Service at this time has a number of such men, and when a man of this kind is needed in a particular place his services are immediately available. (5) The supplemental quarantine work, invariably performed by medical officers of the Service engaged in the medical examination of arriving aliens, is an important factor in the advantages of the national control of quarantine. In other words, the public at large, the maritime interests, and the quarantine function at a given port must receive in the long run great benefit from having both the quarantine and immigration examination conducted by the same set of officers in a uniform manner. (6) In the matter of expense, it would appear that if a State would ask the nation to conduct its quarantine service, simply to save money, the only benefit to accrue would be to the maritime interests and to the individual State. On the other hand, if a State would elect to transfer the quarantine function to national control, in order that the money previously spent for maritime quarantine purposes could be diverted for the betterment of intrastate sanitary conditions, then this reason alone would seem sufficient for every State turning its maritime quarantine over to the nation as a whole. It may be mentioned as a reason for national control of quarantine that no fees are charged to vessels, either for inspections or for quarantine treatment. This fact may be of some interest to the steamship companies, and would doubtless be given by them as an important reason for national, as against State, control. (7) An important feature in connection with the national control of quarantine is the fact that the subject is being closely studied from many standpoints, and the Hygienic Laboratory at Washington is being called into constant use for the purpose, not only of giving technical instruction to officers, but of simplifying the regulations and restrictions in accordance with the growth of knowledge as to quarantinable diseases and their methods of transmission. Then again, by the intimate touch which the Bureau at Washington keeps on the work going on at the various quarantine stations, the carrying out of quarantine regulations by rule of thumb methods is being discarded and quarantine at individual ports, indeed at times on individual vessels, is being carried out with special reference to the actual conditions existing at the time.

Harvey Society Lecture.—The eighth lecture in the present course of lectures given under the auspices of the Harvey Society will be delivered at the New York Academy of Medicine on February 3, at 8.30 P.M., by Professor T. W. Richards of Harvard University. His subject will be "The Relations of Modern Chemistry to Medicine."

The New York Society of Anesthetists will hold a meeting at the New York Academy of Medicine on February 7 at 8.30 P.M.

Hospital Will Pay Visiting Staff.—The Hospital for Deformities and Joint Diseases of New York City, of which Dr. Henry W. Frauenthal is physician and surgeon-in-chief, announces that hereafter members of the visiting staff will be paid $300 a year. The directors of this hospital are of the opinion that it is only fair that medical services should be paid for as well as other help employed in any operating hospital. It is planned to raise this amount to $500 in the near future.

Another Mouse Cancer Cure.—A despatch to the *New York Times* states that Ehrlich says that a mouse cancer cure which he has devised is more positive in its results than that announced a few weeks ago by von Wassermann. It is reported that Ehrlich has obtained 100 per cent. of cures in the mice treated, including not only those artificially infected but those having cancer of spontaneous origin. It is also announced that henceforth Ehrlich and von Wassermann will cooperate in their work on the cancer problem, although continuing their researches in their respective laboratories.

The Army Canteen.—It is announced that more than twenty physicians of Boston have added their names to the petition asking for the restoration of the canteen in the Army. This petition now has the signature of 279 men prominent in medicine and surgery throughout the country. A similar petition has been signed by 2,386 army women, wives, mothers, and daughters of officers and enlisted men. No stronger argument in favor of the canteen could be made than the petition of these women who have the best opportunity to know whether the condition of the enlisted men has been improved or injured by the prohibition of the canteen.

Report of Hebrew Charities.—The annual report of the United Hebrew Charities of New York called attention to the fact that of $40,500 disbursed for relief purposes 20 per cent. was due to the ravages of tuberculosis. This is an increase of $8,000 over the amount given for this purpose during the year 1910. From this the committee concluded that this city is not making much progress in stamping

out tuberculosis. An experiment carried on for two years with thirty-five families, whereby they were moved into sanitary apartments, showed that some sufferers could be cured in their own homes. The society's deficit has grown during the year from $15,000 to $33,000.

American Society of Sanitary and Moral Prophylaxis.—A regular meeting of this society will be held at the New York Academy of Medicine, Thursday evening, February 8. The following papers will be presented: "A Report of the Progress of the Movement," by Prince A. Morrow, M. D.; "A City-wide Investigation of Vice and Its Diseases in Baltimore," by Dr. Donald R. Hooker; "The Reduction in Vice in Many of the Western Cities through Administrative Reforms," by Wirt W. Hallam of the Chicago Vice Commission.

Laboratory for Mount Sinai Hospital.—At the annual meeting of the Directors of Mount Sinai Hospital on January 29, it was announced that the pathological laboratory, for the construction of which Adolph Lewisohn gave $130,000 some time ago, will be begun in the near future. It was also announced that the hospital had closed negotiations for two more lots opposite the present Administrative Building where it has purchased in all fifteen lots.

The Pueblo County Medical Society, at its meeting in Pueblo, Col., on January 18, elected the following officers: *President*, Dr. M. J. Keeney; *Vice-Presidents*, Drs. Bon O. Adams and Harry B. Killough; *Librarian*, Dr. R. W. Corwin; *Member of Board of Censors*, Dr. W. L. Dorlan.

The Medical Society of Franklin County (Pa.) held its annual meeting in Chambersburg on January 16. The following officers were elected: *President*, Dr. Frank N. Emmert of Chambersburg; *Vice-Presidents*, Drs. Guy P. Asper and A. B. Sollenberger of Waynesboro; *Secretary and Reporter*, Dr. John J. Coffman of Scotland, reelected; *Assistant Secretary*, J. Elmond Kempter of Chambersburg; *Treasurer*, Dr. Johnston McLanahan of Chambersburg, reelected; *Censor*, 1912 to 1914, Dr. J. Burns Amberson of Waynesboro.

The Northern Medical Society is the name of a new society in New York. The following officers have been elected: *President*, Dr. William J. Robinson; *First Vice-President*, Dr. A. L. Goldwater; *Second Vice-President*, Dr. Alex. Goldman; *Corresponding Secretary*, Dr. H. Schumer; *Treasurer*, Dr. M. Aronson. Meetings will be held monthly.

Obituary Notes.—Dr. William Asa Wheeler of Portland, Me., a graduate of the Medical School of Maine, 1859, and also from the College of Physicians and Surgeons, Columbia University in 1877, died at his home January 20, at the age of 58. In 1892 he was commissioned a surgeon in the United States Marine-Hospital Service and in 1893 was placed in charge of the medical department of the United States Immigration Service on Ellis Island, which position he held until 1896. He was at one time professor of descriptive and surgical anatomy in the medical college at Evansville, Ind., and when stationed at Buffalo held the chair in surgery in the Niagara Medical College. In 1893 he was sent by the United States Government to study the emigration methods in various European ports.

Dr. Harris A. Slocum of Philadelphia died of apoplexy on January 15 at the age of 54 years. He was graduated from the Medical Department of the University of Pennsylvania in 1879 and was for many years professor of gynecology in the Philadelphia Polyclinic.

Dr. James McKee, superintendent of the Central State Hospital of North Carolina, died suddenly on January 10 at the age of 67. He practised his profession for many years in Raleigh, was trustee of the Rex Hospital, and for six years secretary of the State Medical Society.

Dr. John Augustus Lamson died at his home in Boston on January 16 at the age of 80 years. He was graduated from Dartmouth College in 1853 and from the medical department of Harvard in 1856. During the Civil War he was surgeon of the Forty-second Regiment of Massachusetts Volunteers, and later chief physician in the Discharged Soldiers' Home. He served two years as a member of the Legislature, and in 1880 was appointed chief medical examiner of the Equitable Life Assurance Company for Boston and eastern Massachusetts.

Dr. Charles H. Terry, a graduate of the Albany Medical College in 1864, died at his home in Brooklyn on January 18 at the age of 67 years. He was a Civil War veteran and for many years a surgeon of the New York Police Department. He was a member of the New York State Medical Society, the Kings County Society, and the Brooklyn Pathological Society.

Dr. Edwin W. Bennett of San Francisco died suddenly on January 9 at the age of 65.

Dr. Ernest C. McGouldrick, a graduate of Yale University in 1900 and of Johns Hopkins Medical School in 1904, died in Machias, Me., on January 12 at the age of 37 years. He was a member of the medical staff of the Eastern Maine General Hospital.

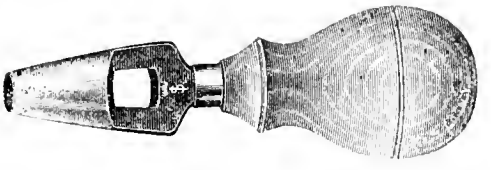
Dr. Charles Hilliard Prague died at his home in Chicago on January 11. He was born near London, Eng., graduated from McGill University, Montreal, Que., in 1867, and served as a surgeon during the Civil War. He was one of the attending physicians to Governor Altgeld during his last illness.

Correspondence.

THE REPAIR OF RUBBER GLOVES

To the Editor of the Medical Record:

Sir: In a large hospital the number of rubber gloves used is so great that even a small detail which tends to economy of time in their repair is of considerable importance. The feature here recorded not only facilitates the repair of a glove, but also renders a repaired glove safer for use in an operation.



In mending rubber gloves, the needle punctures and other small holes are usually repaired by the application with rubber cement of small round patches cut from gloves that are useless. To cut these patches with scissors, as is usually done, not only requires considerable time, but leaves the patches with somewhat ragged edges, which easily become loosened, and frequently result in detachment of the patch. We have adopted at the New

York Hospital punches for cutting these patches. They have been in constant use for two years and have proved very satisfactory, as perfectly round patches may be quickly cut. It is essential to have the punches sharp; as a rule, they can be used for about ten days. We have two sets of punches on hand, so that while one set is in use the other may be sharpened. The cutting is done on a soft rubber block ½ inch thick, but wood is almost as satisfactory. It has been found unnecessary and a disadvantage to use any device such as an embroidery ring to stretch the rubber during cutting. The punches we use are known to the trade as "arch" and "belt" punches. A great variety of sizes are on the market, but the most useful are those which cut patches ¼, ½, ¾, and 1 inch in diameter. By attaching a wooden handle the manipulation of a punch is rendered very easy.

NEW YORK.

THE GENTLENESS OF DEATH.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The editorial on Euthanasia in a recent issue caused me to look over some old medical literature on the subject of death. The best chapter on the subject in my opinion is to be found in Dunglison's "Physiology," published in the year 1838.

Your two last sentences especially attracted my attention: "Immediately death impends, the end is almost invariably benignant and peaceful. What, indeed, is there in all the cosmos so composed and content as the face of the dead?" Dunglison particularly dwelt upon this phase of the subject in the following words: "Perhaps one of the most beautiful and accurate pictures drawn by Byron is his description of the serenity of countenance observable in most fresh corpses; an expression which, by association, is deeply affecting, but not without its consolation to the friends of the departed:

'He who hath bent him o'er the dead,
Ere the first day of death is fled;
* * * * * * * *
Before decay's effacing fingers
Have swept the lines where beauty lingers;
And marked the mild angelic air,
The rapture of repose that's there;
The fix'd yet tender traits that streak
The languor of the placid cheek;
And but for that sad, shrouded eye,
That fires not, wins not, weeps not now;
And but for that chill, changeless brow,
Where cold obstruction's apathy
Appals the gazing mourner's heart,
As if to him it could impart
The doom he dreads, yet dwells upon:
Yes, but for these and these alone,
Some moments, ay, one treach'rous hour,
He still might doubt the tyrant's power.
So fair, so calm, so softly seal'd,
The first, last look by death reveal'd.'
—Byron's Giaour."

ROBERT E. COUGHLIN, M.D.

BROOKLYN, N. Y.

SCHOOL EXAMINER IN THE HOME—A BAD PRECEDENT.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The average physician's lot in Philadelphia, unless he is a school examiner, must be like that of the policeman, unhappy, and, as in *Pinafore*, the babies will be mixed up by a system. I note in a recent issue of the MEDICAL RECORD that a nurse, if necessary, will follow the child into its home to see that the school physician's orders are complied with! We do not know how much of this enforced medical attention the Philadelphia people will stand, but it will inevitably at times give rise to disputes, if not to hair pulling, between the matron and the young lady in uniform, and the trained nurse will be put to flight.

On the other hand, she may be welcomed in place of the family physician, and asked to look at Tommy, who is not of school age. Tommy has a fever and the nurse does not resist the temptation to prescribe, and the mother is saved the expense of calling in a physician. A prescription is not necessarily written.

But for sickness among children the average doctor's income would be even much lighter than it is. The Philadelphia plan makes a "puller" of the nurse for the school doctor, or examiner, and will thereby indirectly cause friction between the family physician and the school doctor. This gratuitous and enforced hospital extension into homes is against the spirit of what was once known as the constitution. Formerly a house could not be invaded without a warrant, based on cause, with particulars.

ACME, W. VA.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HUNTERIAN ORATION—TUBERCULOUS DISEASES OF THE JOINTS IN CHILDREN—INSURANCE ACT.

LONDON, January 12, 1912.

THE annual oration at the Hunterian Society was delivered on Wednesday evening by Mr. Ch. A. Ballance, who devoted it to "Resources of Surgery in Certain Emergencies." No one is, perhaps, more capable of dealing with the progress that has been made in late years in grave emergencies and the formidable operations that have been attempted to meet them, and he spoke with confidence of the advances we may anticipate in the future, the examples he quoted in the various experiments being most encouraging. The foundation of cardiac surgery, he considered, was laid by the experimental work of Block in 1882. The most astounding instance of operation on the great blood-vessels was the removal of a clot from the pulmonary artery by Trendelenburg. He made an opening into the patient's thorax at the level of the third rib, laying bare the great cardiac vessels and, with a curved sound, lifted them sufficiently to enable him to carry out his purpose. He then made an incision in the pulmonary artery and removed four clots, one of which measured 14 inches. Artificial respiration had to be employed while the edges of the wound were held together by forceps. Suturing followed when practicable. The patient survived for thirty-seven hours, death resulting from persistent hemorrhage from the internal mammary artery. The orator expressed a hope that the time was not distant when surgery would prove as valuable within the thorax as it was in the abdomen.

Tuberculous joint diseases in children was the subject of the set discussion last month at the section for children's diseases. The surgical measures that have been or may be employed were mainly considered. Mr. A. H. Tubby opened with a paper pointing out that in children there was not the limitation to extension of the diseased process which existed in adults. The fibrous barrier which limited the process favored the formation

of abscesses and these are more responsive to aspiration and injections of iodoform or camphorthymol. Conservative treatment was to be preferred on the whole to operation. Excision of the hip was not a successful operation, and of the knee little better. The main function to be preserved in those was to carry weight. In the upper extremity complex movements were so important that operation at an earlier date might be considered.

Sir A. Bowlby followed, and stated the results to be obtained without operation. In children growth of new bone was remarkably rapid and suppuration was rare. Even the soft parts in the child repair in a way unseen in the adult. But much depends on the general health and the nutrition, which claim close attention. Rest for a time to the joint, fresh air, and all hygienic conditions for the system. The danger of abscess was septic infection. When large septic sinuses had been formed he saved many limbs by care of the child's general health, and so he amputated less and less often even for desperate cases. More hospital accommodation in the country was greatly needed.

Dr. Butler Harris treated of tuberculin and did not attach importance to the strain. The opsonic index did not differ as to this. He collected from thirteen hospital records which gave divergent results. His conclusion was that, on the whole, small doses of tuberculin accelerated the recovery of cases by surgical rest in hygienic conditions.

Mr. Robert Jones said tubercule in the child thoroughly attended to in the early stage ran a benign course. Absolute rest to the joint, good nutrition and country air, plenty of it, were required. He would keep the children out of doors continually. They were often taken out of splints much too soon. If an abscess came to the surface a small aseptic puncture was enough.

Sir Watson Cheyne so seldom operated now that he sometimes thought these tuberculous joints in children might take a milder course than formerly. But he admitted one could not put out of mind altogether that sometimes operation might be necessary. For abscesses he relied on asepsis and antisepsis, opened freely, and scraped them out. He used tuberculin, thinking it did no harm, but he could not say he had seen it do good. If all cases were treated in country hospitals he thought 95 per cent. of recoveries might be expected.

Mr. Jackson Clarke thought many cases of recovery in infancy recurred in later life. He had not seen a case which had resisted other treatment gain any benefit from turberculin.

Mr. Sutcliffe spoke of the time required for healing—four or five years—for a hip or knee. These did best if kept in bed for many months. He had used tuberculin, but had not seen any definite benefit from it.

Mr. E. M. Corner's experience with tuberculin agreed with that of previous speakers. An abscess case would sooner or later, he believed, come to operation. He opened, washed it out, and used temporary drainage. The cases which recovered without operation he suspected might be nontuberculous. Many were, perhaps, infected by some other organism. Further, some successful cases under tuberculin might not be due to that treatment but to some other factor.

Mr. Lockhart Mummery was for conservatism. If he had to operate he did as little as possible, merely opening an abscess by a small incision, removing any caseous matter, and suturing the wound at once. If septic infection occurred he scraped the sinuses, plugged with gauze soaked in formalin (5 per cent.). This often gave good results.

That the Insurance Act continues to be the chief concern of the profession is shown in the fact that Mr. Ballance gave it consideration in his Hunterian oration on Wednesday. He said medical men had of late been driven back on the primitive instinct of self-defence, but that was neither the last nor the first motive for union. The British Government had passed a law through Parliament professing to provide medical attention for fifteen million people, but we all knew that the act as it stands could not do so, and to place the service under medical control was the only way to make it successful. The government sanctioned the abominable slavery of medical men under laymen, and would fasten the hateful yoke of contract practice on thousands, reducing them and their families to penury. Medical attendance was entitled to fair remuneration as much as any form of State service, but there was nothing in the Act on this point. It would be interesting to note what the legal profession would say to a proposal to compel them to give their services for a capitation fee of 4 shillings per annum. The medical aspect of the act of the problem was purely medical, and any attempt to control or inspect treatment by laymen was a gigantic fraud on the people and an intolerable oppression of those engaged in the most self-sacrificing of all callings.

The meeting of West End practitioners, which I informed you was to be held to form a society to insist on reform of the Council of the B. M. A., took place on Tuesday afternoon. About 250 were present and Dr. Fred. J. Smith took the chair. A society was formally constituted under the name of the "Reform Committee of the B. M. A.," perhaps an unfortunate term, as it appears to exclude nonmembers of that association. Above 100 members of this "committee" were enrolled, and an executive committee was appointed and is already at work. Yesterday it issued a manifesto to the "medical profession in general, and to the British Medical Association in particular," inviting those in sympathy to establish branches of this in the several divisions of the B. M. A., for this committee is determined to work within the Association and desires all its supporters who are not members to become so. In short, it appears that the name adopted, if clumsy, fairly expresses the intention, which is to "end or mend" the council of the Association, as one put it, or to "get rid of it root and branch," as another urged, at the meeting. The executive will confer as soon as possible with any or all the other medical organizations dealing with the situation created by the Act with a view to union. From some aspects it looks as if this committee might not as well amalgamate with the Manchester Union, but in other respects it is too bound up with the B. M. A. for that. The manifesto says the committee exists solely to enforce the avowed policy of that body rather than the more recent weakened version of its Council, and will only contrive to exist until the profession's interests under the Act are adequately guarded "without evasion, equivocation, or mental reservation." The committee holds that the Council was influenced by political considerations to endanger professional interests, is directly opposed to the idea of leaving things to be dealt with

by regulations as the Council now weakly advocates. To attain their end the committee proposes to promote an amending act through Parliament to embody the six points of the original B. M. A. plan. It will certainly require the union of all the societies now to work to pass such an act.

The B. M. A. itself, you know, is canvassing for a pledge to work only as local practitioners may agree as medical committees, not under the thrall of the clubs and with the six points virtually conceded, though not included in the Act. It is reported that they have pledges enough to render the Act unworkable unless so much is agreed to. The *Practitioner's* pledge goes further, but has not so many signatures—estimates 22,000, against 17,000.

Yesterday a committee of the Royal College of Surgeons was appointed to report at the next council meeting as to the position of Fellows and members under the Act, in the meantime consulting with other committees of other societies formed with similar objects.

I have only mentioned some of the many important utterances. I may add that the newspapers are daily giving columns to the campaign. It is to be hoped all this publicity will eventually add to the prestige of the profession, but the papers almost invariably reflect their political bias. A comparison of numerous assertions and revelations forces the conclusion, now generally adopted, that the Council could at one time have defeated the bill, but its negotiators gave way rather than bring about the fall of the government.

It is said that one can boast of having the oldest doctor in the world as a British subject and a magistrate to boot. He lives in Essex, on the Bench of which county he has sat for 60 years. His name is Edgar Jones, and he has just entered on his one hundred and third year. Sometimes I have asked myself whether some of our aged friends may have made a mistake in the date of their birth, as I have found they relied on their recollection of their parents' memory. However, Dr. Jones belongs to a long-lived family; his father died at 92, his eldest brother and sister both passed their 90th year, and a brother still living is nearing his one hundredth.

Progress of Medical Science

The Gas Bacillus as an Agent of Intestinal Fermentation and Diarrhea. H. F. Hewes and A. I. Kendal.
The Treatment of Tuberculous Adenitis with Report of Fifty-six Cases from the Tuberculosis Department of the Massachusetts General Hospital and from Private Practice. J. B. Hawes, 2d.
Nitrous Oxide-Oxygen Anesthesia, with a Description of a New Apparatus. W. M. Boothby.
Relation of Thigh and Leg Muscles to Malpostures of the Feet. C. L. Lowman.
Hemorrhage from the Throat. A. C. Getchell.
Case I: Status Lymphaticus. Case II: Syphilitic Infection Involving the Floor of the Fourth Ventricle. F. S. Crossfield.
Two Cases of New Growth Involving the Eustachian Tube. P. C. Proctor.
An Unusual Tumor of the Fauces. E. E. Foster.

The Gas Bacillus in Intestinal Fermentation and Diarrhea.—H. F. Hewes and A. I. Kendal state that in certain cases of colitis the gas bacillus apparently finds a very favorable field for activity, causing marked fermentation of carbohydrate food with much augmentation of the diarrhea. How far a control of the activity of the gas bacillus, by the proper use of diet, may influence the actual cure of the pathological condition present in these cases can be determined only by further study. If, as is quite probable, this activity of the gas bacillus is simply an associated condition, in the course of the colitis, the special treatment of this one factor may have no permanent influence on the condition of colitis. But it will certainly do much to lessen the diarrhea and thus benefit the patient. It would seem probable, since the gas bacillus can play a secondary part in the maintenance of diarrhea in colitis, that it may be a not uncommon cause of diarrhea in many cases not associated with such severe pathological conditions of the intestinal mucosa as a colitis or dysentery, for example, in the numerous transitory conditions of diarrhea lasting from a few days to a few weeks, in which the discovery of the organism and the consequent application of the proper treatment may result in a prompt and complete relief of the condition.

Treatment of Tuberculous Adenitis.—J. B. Hawes, 2d, states that to get good results in the treatment of tuberculous adenitis it is more important to treat the patient than to devote one's attention solely to the tuberculous process in the glands. The physician should not depend upon surgery alone, hygiene alone, or tuberculin alone, but should use all or each of these measures as is required by the individual patient.

Nitrous Oxide-Oxygen Anesthesia.—W. M. Boothby notes that the first attempt to give a public demonstration that the body can be safely rendered insensible to pain for surgical procedures was made in Boston by Horace Wells, a dentist of Hartford, Conn., with nitrous oxide in December, 1844, or January, 1845, nearly two years before the demonstration of ether by Morton at the Massachusetts General Hospital, on October 16, 1846. Nitrous oxide-oxygen anesthesia, with the addition of such minimal quantities of ether vapor as may be needed, is, Boothby maintains, the anesthetic of choice. The general use of this anesthetic is necessarily dependent on the perfection of an apparatus which will overcome the many and peculiar mechanical and operative difficulties attending its administration. Such an apparatus for the giving of those combined anesthetics is described by the author.

Malposture of the Feet.—C. L. Lowman concludes from his investigations that positions of the knee and thigh in relation to the weight line and as affected by the action of the external rotators of the thigh have a marked effect on that malposture of the foot known as "pronation" or valgus.

Hemorrhage from the Throat.—A. C. Getchell states that the spitting of blood to the amount of a teaspoonful or more is to be attributed to pulmonary tuberculosis, and a general practitioner who assumes that the blood comes from the throat, which he cannot see, because he fails to find evidence of disease elsewhere, takes a position which cannot be justified by correct practice; and the laryngologist who allows himself to give an opinion that the blood comes from the throat, without direct visual evidence of the fact, and also an exhaustive study of the general condition of the patient, commits a similar error.

Status Lymphaticus: Syphilis Involving Floor of Fourth Ventricle.—F. S. Crossfield reports cases of these conditions.

New Growth Involving Eustachian Tube.—P. C. Procter reports a case of carcinoma involving the pharyngeal end of the Eustachian tube; and also a case of a growth in the same locality, which growth consisted of inflammatory tissue which could not be identified, being either adenoid tissue or lymphosarcoma.

Unusual Tumor of the Fauces.—E. E. Foster reports the case of a woman aged sixty years from whom was removed a tumor slowly growing in the region of the right tonsil. The appearance was similar to that of a peritonsillar abscess without the signs of inflammation. The tumor was identified by Councilman as a colloid carcinoma, very suggestive of the type of tumor seen sometimes in the parotid gland.

Dr. Edward G. Janeway.—S. A. Knopf describes the manifold activities of the late Dr. E. G. Janeway in furthering the antituberculosis cause.

Medicine and the Law.—J. H. Gleason considers the physician as a witness and as an expert; as to his duty in reference to death, as to his responsibility for the betrayal of the professional secret, for neglect, imprudence, ignorance, or want of skill in the practice of his profession; also the physician's relation to the criminal law respecting operations or mistakes resulting fatally, and as to the concealment or nondisclosure of crime discovered in the course of his practice.

Uterine Fibroids.—A. Stein reports two cases of this condition in which the sudden onset of the pains was suggestive of peritonitic manifestations and in which immediate operation was imperative. In both cases there were multiple fibromyomata, all of which presented the same clinical picture. In the first case the intramural fibromyoma was of such strikingly soft consistence that at first the possibility of pregnancy was suspected.

Fixation of the Kidney.—F. McK. Bell describes a new operation that he has devised for this purpose.

Congenital Pyloric Obstruction.—H. Lowenburg discusses the various phases of this subject.

Hysterical Rabies.—T. A. Williams reports two cases of simulated hydrophobia in which the hysterical mechanism was distinctly evidenced.

Prostatectomy.—J. A. Gardner believes the suprapubic operation is the ideally conservative one, because it is anatomically correct; the offending part is easier of access by this route; the obstruction is completely removed; control of the urine is regained with no dribbling, and the ejaculatory ducts are presumably not injured.

The Movable Cecum.—C. A. Roeder states that a movable cecum may be productive of symptoms resembling chronic appendicitis. A high cecum may be a movable cecum producing symptoms. On finding only a kinked appendix and a pronounced anterior ileocecal fold, one should look for a prolapsing cecum and a Lane kink. The type of constipation produced by a prolapsed cecum may be due to traction on and narrowing of the ileocecal valve. Some cases of pylorospasm may be due to narrowing of the ileocecal valve by traction of the cecum. Wilm's cecopexy, Murphy's sigmoidopexy, Lane's ablation and anastomoses, all efforts to relieve stasis, show a variety of opinions on surgery to remedy functional conditions of the colon and indicate the necessity for further study.

Conservation Department in Hospital and Dispensary.—M. J. Schoenberg states that the teaching of the principles of conservation of health is the real and most important task of the medical profession of to-day. This teaching can be effectively carried out in hospitals and dispensaries.

Kraurosis Vulvæ.—C. F. Kivlin reports a case of this condition in which he performed the following operation: Commencing from above, outside the diseased tissue, he dissected away the whole diseased tissue, excluding the hymen, the incision starting on the right side and from above. He came down upon the posterior commissure and upon the left side after the diseased tissue had been removed. He dissected the posterior vaginal and lateral wall for about one inch, and cut partly through the external perineal muscle so as to have a large vagina. He then sewed the vaginal mucous membrane to the healthy skin. The patient made a good recovery.

The Urine in Gout.—S. R. Klein discusses this subject from the viewpoint of diagnosis.

Deep Injections of Alcohol in Trifacial Neuralgia.—H. T. Patrick describes the technique of deep injections of alcohol into the fifth nerve and its different branches for trifacial neuralgia. The ophthalmic nerve is not suitable for the injections, as there are other important vessels and nerves too near to permit them to be used with perfect safety. Superficial injections of the supraorbital nerve have been usually successful. It is usually easily located by pressure over the supraorbital notch, but if this cannot be found the operator must rely on his anatomical knowledge and the distribution of analgesia after the injection. The supratrochlear branch of the frontal nerve may have to be separately injected. It may be reached at a point about midway between the inner canthus of the eye and the eyebrow on a line running upward and inward at an angle of about 45 degrees. The solution used is muriate of cocaine 2 grains, alcohol 2½ drams, and distilled water sufficient to make ½ ounce. The author prefers not to use an anesthetic, as the sensations of the patient are of great assistance in locating the injections and showing its results in the production of anesthesia or analgesia in the distribution of the nerve. He likes to wait two or three days before repeating the injection, but has given a second in twenty-four hours, and even a third on the second day after.

The Control of Typhoid Fever.—M. L. Price, W. R. Stokes, and C. W. G. Rohrer have devised special outfits which, with directions for their use, are left by the inspectors with the attending physician, nurses, or attendants. The inspector is supposed to see that these are instructed in the use of the materials and he may add as many oral instructions to those given in the circulars as he thinks best. After the case is over he collects the utensils which after cleansing and disinfection are used again in other cases.

Anesthetics.—M. Metzenbaum states that chloroform must be considered a dangerous anesthetic even in the hands of an expert. Ether is administered best by the drop method. By this method ether can be used more universally than any other known anesthetic. From 1/200 to 1/100 grain scopolamine combined with ⅛ to ¼ grain morphine should be given by mouth or hypodermically one-half hour before general anesthesia, excepting in very young or elderly patients or in those with fever.

Operating Cystoscope.—H. Meyer describes a new operating cystoscope which embodies the priniciples of clamp and cautery in one, acting simultaneously, and ac-

complishing as much at one sitting as is required by two or more sittings with the Nitze instrument. It eliminates the snare problem and is much easier to learn and can remove small foreign bodies or crush small vesical calculi.

Exophthalmic Goiter and Symmetrical Lipomatosis.—L. Neuwelt reports the case of a man aged forty-two years in whom both of these conditions were present.

Typhoid Fever Traced to Milk Infection.—E. O. Jordan and E. E. Irons report three outbreaks of typhoid fever resulting from milk infection.

Strangulated Femoral Hernia.—J. Douglas states that, because of the danger of strangulation and inability to cure by other than operative measures, operation should be advised when a diagnosis of femoral hernia is made. Sufficiently early diagnosis and operation would prevent the necessity of intestinal resection, and thus lessen the mortality. Intractable vomiting with pain, either abdominal or localized in the groin, especially in women, should indicate careful examination of the femoral rings, even before it is obvious that intestinal obstruction exists. Operation should be performed as soon as the diagnosis of strangulated femoral hernia is made, if gentle attempts at reduction fail. If the strangulated intestine is damaged beyond viability, resection and anastomosis should be performed. When there is a sufficiently long mesentery not to hamper the operation, this may be done through the primary incision made over the femoral ring; otherwise, a secondary abdominal incision should be made. Except in the most desperate cases, when the patient's condition is so extremely bad that it is impossible to perform an anastomosis, an enterostomy, even as a temporary resort, should not be done.

Hygienic and Therapeutic Value of the Open Air.—H. Sewall notes that no proof has been furnished that the increase of carbon dioxide, the decrease of oxygen, or the addition of organic animal matter in the air of ill-ventilated apartments is, under any ordinary circumstances, injurious to health. It has been proved that such chemical changes are not the cause of the sensations and symptoms due to poor ventilation. The subjective and objective effects of close air are the result of the combined elevations of temperature and the humidity incident to the association of living bodies. It is argued that the temperature nerves of the skin are specific sense organs for the appreciation of the variations of temperature and humidity, through which nerves a wide range of metabolic actions in the body is regulated. It is through the genius of the moving air of the open that the temperature nerves find their most salutary stimulus and induce forms of metabolism characteristic of highest mechanical efficiency in the body. The physiological difference between "open" and "closed" air depends partly or wholly on differences in the stimulation of the temperature nerves of the skin under the two conditions. The environment of the open air is conducive to an esthetic state that should not be ignored as an aid to healthy living.

Anaphylaxis.—St. G. T. Grinnan emphasizes the importance of the study of this phenomenon, especially with reference to the use of vaccines and antiserums.

Vomiting in Infants and Children.—H. Lowenburg discusses the causes and treatment of the different forms of vomiting in infants and young children.

Neurotic Basis of Juvenile Delinquency.—By P. K. Brown. (See MEDICAL RECORD, Vol. 80, page 107.)

Cholera Carrier.—R. H. Creel presents the history of a sailor on a transatlantic liner from Italian ports who was found to be carrying the cholera vibrio. He was under examination at the New York quarantine station from August 17 to September 27 and was treated for the condition. The conclusion held was that the vibrios were contained in residual masses of fecal matter, which were evacuated by purgation, thus explaining the irregularity of the findings in the stools.

Vaccine Treatment of Chancroids.—R. H. Herbst and L. C. Gatewood state that in a majority of the cases of chancroids examined they have found an organism belonging to the pseudodiphtheria group, in some instances almost in pure culture. A bacillus, nonpathogenic, belonging to this group, and morphologically identical with what the authors have found is commonly present in the urinary tract and on the genitalia. Clinically, one rarely sees chancroids in clean individuals, while in dispensary practice they are very common. In other words filth seems to play an important rôle as an etiological factor. The authors suggest that vaccine treatment may be of value.

The Lancet.

January 13, 1912.

Relationship of Tuberculosis to Accident and Injury.—By W. Cecil Bosanquet. (See page 237.)

Sensory Disturbances from Cerebral Lesions.—H. Head and G. Holmes describe the sensory disturbances associated with certain lesions of the optic thalamus, based on a study of 24 cases in which there were sufficient symptoms and signs to justify the diagnosis of a thalamic lesion. The loss of sensation differs in no way from that produced by interference with sensory impulses, either as they enter the optic thalamus or as they pass to the cortex by way of the internal capsule. Put to these familiar defects another factor may be added when the lesion destroys certain parts of the optic thalamus. This fresh factor, which alone can be attributed to the disturbed activity of this organ, is a tendency to react excessively to unpleasant stimuli. The prick of a pin, painful pressure, excessive heat or cold, all produce more distress than on the normal half of the body, and this is the essential feature in all the cases. There is also a greater response to pleasurable sensations on the affected side. The two sides of the body react differently with reference to emotional states. Some loss of sensation is always manifest on the affected half of the body. This is most frequently the case with respect to the appreciation of posture and the recognition of passive movement. Tactile sensibility is diminished in many cases, and localization of the spot touched was defective in half the cases. Sensibility to heat and cold may show all degrees of change from total loss to a slight increase of the neutral zone. The power of estimating the relation between two weights and the appreciation of relative size are frequently disturbed in the abnormal half of the body.

Rupture of the Uterus.—G. Blacker reports eight cases of this condition and concludes that as regards conservative treatment or laparotomy, while in cases of incomplete rupture gauze plugging or vaginal drainage may prove a useful method, in all cases of complete rupture the treatment most likely to give the best results in the future will prove to be abdominal section, followed by the removal of the damaged uterus and the provision of efficient drainage for the peritoneal cavity.

Incidence of Mediterranean Fever in Malta.—J. W. H. Eyre states that following the prohibition of the use of milk from the Maltese goat, and the reduction of the goat population of Malta, there has been a striking diminution in the case incidence of Mediterranean fever among the naval and military forces stationed at Malta.

Electric Metallic Colloids.—B. G. Duhamel states that these are valuable as a means of stimulating phago-

cytosis and of destroying microorganisms and their toxins, in such diseases as septicemia, pyemia, pneumonia, pleurisy, empyema, and meningitis. Injections of 5 to 20 c.c. are made intramuscularly or intravenously. In local lesions injections may be made into the affected tissues.

Treatment of Gonorrheal Conjunctivitis.—J. S. Hosford and G. B. James state that the constant use of the irrigating douche is the primary curative factor. It may be applied either by a mechanical apparatus fastened to the head or by the hands of a relay of properly instructed nurses. These should sit behind the patient's head and apply the unintermitting stream as the surgeon may direct from time to time. No cessation in the flow is to be permitted for a moment either day or night. The solution which the authors found most satisfactory for this purpose is one of permanganate of potash, varying in the early stages from 1 in 15,000 to 1 in 20,000, and in the later stages a solution of boric acid, eight grains to the ounce, may replace this and be all that is necessary. The temperature should be from 85° te 90° F. in the douche reservoir, where a thermometer is constantly prsent. Eight days' continuous irrigation has been found sufficient to bring the case completely under control, provided that the cornea has not been affected.

Psychotherapy.—W. P. S. Branson states that there is only one measure of the suitability of an illness for treatment with the aid of psychotherapy, and that is the measure of its emotional and ideogenic ingredients, provided always that rational faculty is not seriously in abeyance. There is practically no place for it in urgent and acute physical illnesses, nor in the graver developments of chronic ones; for in proportion as physical disturbances are profound emotional ones tend to sink into insignificance. Nor can it be employed for developed psychoses, since an appeal to the reason is the essence of the practice. On the other hand, it is applicable, in a greater or less degree, to a large assortment of chronic maladies of little urgency, however recalcitrant they be to treatment; to neurasthenic states, especially chronic ones; to the milder types of hysteria, and to a great variety of psychical symptoms masquerading as physical diseases.

British Medical Journal.

January 13, 1912.

Auricular Fibrillation.—T. Lewis states that the condition of auricular fibrillation clearly explains the following phenomena: The original rapidity of the pulse and its irregularity, the character of the irregularity, the loss of the auricular wave in the neck, the loss of the P summit in the electrocardiogram, the loss of presystolic murmurs, the presence of rapid oscillations in the venous curve, the presence of oscillations in the electrocardiogram, the varying rate of the ventricle in a single patient or from patient to patient, and the action of digitalis. Each of these is clear once the true explanation of the mechanism is grasped.

Effects of Soluble Digitoxin.—B. Moore states that soluble digitoxin, on account of its solubility in water, can be used for intravenous injection. This solubility prevents any pain or local inflammation, such as is occasioned by injection of alcoholic solutions, and the low toxicity as compared with that of the mixed glucosides in tincture of digitalis renders intravenous administration safe. At the same time a full therapeutic effect, which is very persistent, is obtained on the heart. In administering soluble digitoxin a full therapeutic effect should be aimed at, and thereafter the drug should not be pushed further, but just enough given to maintain the advantage by keeping pace with the elimination of the drug. The heart tracings show that a pure digitalis effect is obtained on perfusing digalen, the therapeutic effect being marked, and the tonus at the end being very considerable. Soluble digitoxin shows none of that hemolytic action which is possessed by those sapo-glucosides which act on the heart, as, for example, the digitoxin present in ordinary tincture of digitalis.

Cane Sugar in Cardiac Failure.—H. Dingle reports the case of a man aged 28 years in whom absolute rest, a suitable diet, and various drugs did not relieve a failing heart. Although the condition was considered hopeless, the administration of cane sugar was resorted to. Five ounces of this substance were given daily with beneficial results. The patient's abdomen previous to that treatment had been tapped on two occasions, when respectively twenty-two and sixteen pints of fluid had been withdrawn. Since the treatment began the patient has required cardiac drugs only for a few days and has not required further tapping.

Infection by Leptothrix Bacillus.—J. M. Clarke and G. Scott-Williamson report a case of continued fever of obscure origin, running a course of a little over three weeks, with marked symptoms of disturbance of the nervous and also of the urinary system. It appears to have been due to a leptothrix bacillus not previously described as a pathogenic organism except in a case of pyemia and meningitis recorded by J. Ritchie and S. McDonald, and in five other cases met with by the latter during an epidemic of cerebrospinal meningitis. These cases were all fatal.

Testing of Color Vision.—W. M. Beaumont points out the advantages of the Eldridge-Green lantern over Holmgren's yarn in the testing of color vision. The advantages of the lantern are that it is simpler to apply; the colors do not fade or get soiled by time or use; the lantern is a method of testing which resembles the actual signals in use by land and sea, and the obscurity produced by distance, fog, mist, or rain can be closely imitated. The two signal colors are red and green. The lantern can be arranged to show the red as seen on a foggy day; some color-blind men, while recognizing the red as red under ordinary circumstances, will call it green when it is modified by fog. By varying the size of the diaphragm aperture one can represent the bull's-eye signal lantern as seen at 600, 800, or 1,000 yards. A congenital case of total color-blindness is rare, and more so is the acquired form. A one-sided lesion in the color center is occasionally met with. It is well recognized that there are symptoms which point to intracranial pressure which precede papilledema and among these are changes in the recognition of color. The importance of these prepapilledematous symptoms lies in the fact that the tendency of present-day surgery is in the direction of early decompression operations.

Corneal and Absolute Astigmatism.—J. Rowan notes that out of 1,000 eyes examined by him the absolute astigmatism and the corneal astigmatism were the same in 475 cases—that is, 47.5 per cent.; 230 were hypermetropic, 353 showed compound hypermetropic astigmatism, 89 were myopic, 100 showed compound myopic astigmatism, and 138 mixed astigmatism.

The Administration of Oxygen.—L. Hill points out the inefficiency of the nozzle and funnel methods of administering oxygen, for the latter diffuses into the air and the patient inspires air enriched very slightly with oxygen. A tight-fitting mask has the disadvantage that

it cannot be borne by patients who are ill and fretful, as with pneumonia. The problem is to contrive a mask which will allow a patient with pneumonia to receive an efficient supply of oxygen and yet will not render him uncomfortable or fretful. The author has devised a celluloid facepiece to which a curtain of washable material is attached. The handle of the mask is also the inlet tube for the oxygen. The current of oxygen flows over the mouth and nose of the patient. The current is turned on until an agreeable cooling effect is obtained, and no sense of closeness is felt when the mask is applied to the operator's face. The operator, by applying the mask to his own face, will soon get to know the right degree of hissing noise in the tube. The patient inspires the atmosphere confined under the mask, and, as a current is used sufficient to blow away the CO_2, a very high percentage of oxygen is obtained in the alveolar air, for example, over 70 per cent.

Berliner klinische Wochenschrift.

January 8, 1912.

Oral Auscultation.—Takata describes succinctly the diagnostic resource which he has been developing since 1907, in Tokio, and which he has demonstrated at the University of Halle in 1911. The technique is simple, for the patient merely holds the end of an ordinary stethoscope in the mouth and breathes slowly and quietly. The opening of the mouth required is that made in saying "ah." The patient is asked to cough as in the course of an examination. It is important that the breath through the mouth, and, if necessary, the nares may be occluded with the fingers. Different râle-like sounds which may emanate from the tongue, palate, larynx, etc., require differentiation from intrathoracic râles. Among the advantages of the method are the following: The ordinary sounds heard through the chest wall may be heard through the mouth without touching or exposing the patient. The number of individual râles heard is much greater and the tone somewhat louder than with ordinary stethoscopy. Heart murmurs are audible, but not pleuritic friction sounds; hence a useful differential test is at hand. The method is used by the author in bronchitis, pneumonia, pulmonary edema, hemoptysis, infarctions, and especially in incipient tuberculosis. Central pneumonia may be detected when nothing positive results from ordinary auscultation. The method is especially useful when a large number of people have to be examined in a short time. The greatest drawback, aside from the need of excluding intraoral and laryngeal sounds, appears to be the sterilization of the mouthpiece between examinations. A large number should be available for a day's work, to be resterilized over night.

Sympathoma Embryonale.—Pick concludes his article on this subject. The tumor in question may be termed an immature or undifferentiated neuroma of non-medullated nerve tissues, and has nothing in common with glioma. It may also be termed a ganglioma. It is very largely an affection of very early childhood, and may be present at birth, but rarely it occurs in adults as well. Nearly every case thus far reported was clinically malignant. Clinically the sympathoma is most commonly a neoplasm in the suprarenal glands of one or both sides. Other lesions may be present in the liver, in the lymph-nodes, or within the cranium, and it may occur isolated in the latter. Its localization is due to the fact that in the embryo the structures from which the sympathetic nerve tissue develops (sympathogons) are very widely distributed. We need not be surprised, therefore, if such tumors are found in unsuspected regions, even if isolated, *i.e.* without localization in the seats of predilection. Pick himself saw a case in the uterus and pelvic connective tissue. The multiple deposits in the liver and the occurrence in lymph-nodes are not necessarily metastatic and may not be metastatic at all, as sympathogons occur in these structures. Histological study shows a sort of progressive scale of evolution. The simplest form, consisting only of unchanged sympathogons, is known as sympathogonoma. With some differentiation resembling the structure of a sympathetic ganglion we have a ganglioma embryonale sympathicum. With further organization a ganglion neuroma would result. Intermediate forms occur. In future so-called sarcomas and cancers in very young children may turn out to belong to the class of neoplasms under consideration.

Nerve Extraction in Gastric Crises.—Franke calls attention to the silence which greeted his announcement, in 1910, of a case of complete extraction of an intercostal nerve for gastric crises in a tabetic. The operation was intended to replace a Foerster's radiculectomy or rhizotomy. He has since operated on two other patients. In all three cases the results were excellent. Prof. Leriche of Lyons has written the author that he has performed two successful operations, so that in a forthcoming report at least five cases will be controlled.

Münchener medizinische Wochenschrift.

January 2 and 9, 1912.

Röntgen Castration.—Von. Herff contrasts this resource with operation castration (female). The latter is the more certain and complete, but it is possible that the artificial climacteric is less severe in Röntgen sterilization—milder and of shorter duration, while the danger to life is very much less, although not wholly absent. The trouble and expense are, or at least may be, far less in operative cases, and the Röntgen patient is also exposed to some collateral action of the rays. From another viewpoint oophorectomy is useful in a much wider range of cases than the competitive procedure. Finally the weight of evidence as to practicability seems thus far to lie with operative castration.

Stenotic Tendovaginitis at the Styloid Process of the Radius.—De Quervain states that this affection, which he described in 1895, occurs by preference in women and without apparent adequate cause, although in some cases it is evidently due to the influence of overwork on a too narrow compartment of the sheath which contains the extensor pollicis brevis and the abductor pollicis longus. The chief symptom is more or less violent pain reflected to both the elbow and thumb. The symptoms may take the form of acute relapses or a single chronic affection. Histologically is found only a thickening of the wall of the tendon sheath compartment involved. The treatment in recent cases consists of cold applications, fixation, pressure bandaging, sometimes in warm applications and revulsion (in insidious cases), while in very obstinate cases in open or subcutaneous tenotomy. All cases thus far reported of operative intervention were cured permanently.

Remote Results and Relapses After Gallstone Operations.—Arnsperger controls 147 cases from this viewpoint. Of this number 13.6 per cent. are known either to have sustained relapses or to have received no apparent benefit from the operation. Of the remainder 64.6 per cent. are known to have recovered fully, while 10.7 per cent. did not recover fully, but are efficient for work. The best results occur when the stones are present in a saceulation or reservoir in which cholecystitis is present. Naturally the results of total extirpation are most favorable. Spurious recurrence is seen when stones form in the liver. After cholecystotomies about one-half the cases give no further trouble as far as overlooked or recurrent stones are concerned. In the others the symptoms are due to adhesions, sclerosis, etc. It is therefore best in all cases of cholecystitis to extirpate the gall-

bladder. There is a distinct field for cholecystotomy when extirpation would prove too formidable an intervention, and also in the case of stones in an intact gall-bladder when the stones are not too large.

Is Labor an Anaphylactic Phenomenon?—Esch considers this interesting problem, the importance of which can hardly be overestimated. For if labor is the sequence of an anaphylaxis the pathology of pregnancy becomes much more intelligible. Esch, however, takes the opposed view as a result of his own experiments. If labor be anaphylactic then the injection of a gravida with fetal or placental serum should cause a reaction; and such a sequence could not be obtained by the author in animal or human experiment. The lessened toxicity of the urine of a parturient also militates against such a supposition. The technique employed by the author in his human researches is of the same order as the von Pirquet tuberculin diagnostic test. The subcutaneous incorporation of large quantities of serum could well produce a catastrophe, although the method seems harmless in animal experiment.

Myoma Heart.—Neu and Wolff decide that there is no specific myoma heart, the lesion so called being an ordinary fatty heart or brown atrophic heart due to hemorrhage and resulting anemia or to the "consumption" caused by a large uterine neoplasm. Brown atrophy occurs in carcinoma, tuberculosis, and exhaustive affections, and is almost constantly present in paralysis; so that there is more justification in calling it a paralytic than a myoma heart. On the other hand, it is by no means the rule to find brown atrophy in myoma, for the lesion may be fatty heart or a combination of the two. This is not denying that the heart must suffer in some manner sooner or later from uterine myoma; for not only will the hemorrhage lead to the so-called albuminosis or fatty degeneration, but every consumption of the tissues will tend to cause brown atrophy of the heart. If the patient is already a cardiac the development of myomata will produce the same degenerative changes.

Antitoxin in Postdiphtheritic Paralysis.—Crohn first refers to the supposed inefficacy of the serum in postdiphtheritic paralyses and in the form of secondary heart failure believed to depend on neuritis of the cardiac nerves. Recently Kohts, disregarding this teaching, continued to inject antitoxin after apparent recovery from the toxemic state and reported brilliant results. The author also reports two successful cases. The original injections were in small single doses, the disease being clinically of mild type. As paralysis and cardiac failure developed in three and six weeks respectively, and did not respond to symptomatic treatment, 2,000 units of antitoxin were injected, with results which could only be regarded as specific in character. The diphtheric sequelæ therefore seem to be due to toxic material generated in the body of residual bacteria or from some at present unsurmised source; or the neutralization may have been incomplete at first or the tissues may have become anaphylactic.

Deutsche medizinische Wochenschrift.

December 21 and 28, 1911, and January 4, 1912.

Chemotherapy of Mouse Cancer.—Von Wassermann and two others at work upon this problem in Gaffky's laboratory state that at present the effort is concentrated on the discovery of some chemical which when injected into the circulation will automatically leave the blood, enter the tumor cells, and destroy the latter. Thus far all attempts in this direction had failed of practical results, but the discovery was made that sodium telluride and sodium selenide, when directly injected, possess a selective affinity for the interior of the cancer cell, their deposition therein being attended by a reduction, with deposition of the metal *in loco*. It appeared also as if both metals and especially tellurium produced a softening and liquefaction of the cells. The salts were injected into the caudal vein, but it was soon apparent that they did not reach the tumor mass when thus exhibited. It was then recalled that the fluoresceïn coloring matters when injected intravenously are able to react and color even the least vascular tissues like the cornea; and it was surmised that the poverty of mouse-cancer in blood vessels was a handicap to the intravenous method. The attempt was therefore made to combine into a synthetic eosin and selenium, and after much labor such a substance was obtained, and the results secured have been in all respects those which satisfy the theoretical requirements. It has become possible to cure a mouse cancer permanently, provided it has not reached a certain magnitude.

Technique of Artificial Pneumothorax.—Forlanini sums up a serial article on his operation as follows: When the nitrogen is first introduced and whenever it is subsequently conveyed into the pleural cavity his method of procedure reduces the danger of gas embolism to a minimum. When first introduced aspiration is usually necessary. If on account of soluble adhesions the nitrogen in the cavity is under pressure the amount of the gas is so small that it could hardly suffice to cause embolism. In consecutive operations it is always possible to control the needle. Compression of the rubber tube makes possible the formation of a pneumothorax in cases of soluble adhesions of the pleura, in which simple aspiration is insufficient. In the same way a needle which has become stopped up during its passage through the thoracic wall is rendered pervious. The author's apparatus now fulfills all requirements. The operation may be performed quickly, the amount of gas pressure can be controlled at all times, and the apparatus is portable and handy to operate.

Treatment of Gout.—Richter is not an adherent of emanation therapy for gout, as he has seen none of the favorable results ascribed to this remedy by others. It may expel the uric acid from the blood, but without thereby influencing the severity of subsequent attacks. Still, the method is in its infancy as yet and he does not discourage its use. Inhalation is the proper method of exhibition. Large doses of HCl, once thought to be eminently contraindicated, are now known to prevent the formation of uratic deposits, and may be given when there is no evidence of hyperacidity. It has likewise been shown that alkalies, so far from rendering uric acid soluble, produce just the opposite effect. Local warmth is a dependable resource and facilitates solution of both uric acid and urates. Colchicum during an acute attack holds its own as a truthworthy remedy.

Case of Pregnancy Toxicosis Cured with Horse Serum.—Freund, having deducted on theoretical or empirical grounds the probable efficacy of normal horse serum in this affection, tested it in a case of multiform toxic dermatosis in a gravida. The eruption appeared a day or so before labor and did not subside after delivery. On the sixth postpartum day it was still active and 25 c.c. fresh horse serum were thrown into the left median vein. A serum reaction promptly followed—chill, high fever, and headache—and persisted for half a day, during which the eruption receded and the itching subsided. This result is believed to have proceeded from a specific activity of the serum, but the rationale is not clear.

A Remarkable Hermaphrodite. — Hirschfeld and Burchard describe the case of what was undoubtedly a male with perfect female external genital organs. The sex diagnosis was made through the discovery of spermatozoids in the urethra. The individual had in part the secondary sexual characters of a female and had been brought up as a girl. Not until the age of 20 did the individual have any doubt as to the sex, although psychically the male type had always been approximated, not

only in choice of occupation and recreation, but in sexual feelings, strong but innocent attachments having been formed with certain girls. At puberty menstruation did not appear, but the voice changed and a scanty beard and moustache appeared, which had been removed by a beauty specialist. Sexual excitement, both when awake and in dreams, was accompanied by erection of the clitoris, and orgasm and ejaculation of a whitish fluid from the urethra. The lines of the figure were feminine throughout, and the breasts were well developed and the hands and feet small and slender. The external genitals were feminine throughout. There was an intact hymen and normal vagina. The uterus was infantile and anteflexed. No ovaries were palpable. The expression of the face, the gait, speech, and handwriting were masculine and the impression made was that of a male. The mental processes were decidedly masculine. The crucial test was found in the urethral ejaculation which contained active spermatozoids. Extreme care had to be taken to exclude the possibility of deception, and a well-known embryologist was one of the scientific men invited to be present, the case having a forensic side in that the correct sex was to be publicly established. The ejaculated substance was shown to be semen and not a mere fluid containing spermatozoids. The sex was affirmed to be male and male clothing was thenceforth worn. The right to marry is questionable, as coitus could not be effected. From this point of view the individual could have married as a woman, for the vagina is quite normal. On the other hand, paternity is possible with artificial impregnation. The case appears to be quite unique.

Medical Men in Germany.—In 1911, according to Prinzing, there were 13,866 physicians registered in Germany, of which no less than 4,083 devote themselves to specialties. The percentage of specialists is increasing steadily. In 1911 their number in proportion to 10,000 population was 6.13, as against 3.37 in 1906. On the other hand, the nonspecialists show a slight decrease, for in 1911 they numbered 6.15 per 10,000, as against 6.67 in 1906. No less than 780 specialists are gynecologists and there are 212 gastroenterologists. The ophthalmologists and laryngorhinologists are about equally represented (over 500 each). Nearly all the nose and throat men treat the ear, while only a small number of eye men do this; and there are but fifty-one exclusive otologists. All the other specialties are well represented. There are 444 exclusive surgeons, while 121 combine surgery with gynecology.

Artificial Adrenalinemia as a Protection of the Skin in Radiotherapy.—Reicher and Lenz, who have written before on this subject, announce their most recent conclusions as follows: When the skin is rendered anemic with adrenalin it is more resistant than normal skin to Rontgen ray and radium radiation, and has withstood a double erythema dose of mild rays for three weeks. In therapeutic deep radiation the strong rays have generally been used, allowing the mild ones to be filtered out. When the skin is rendered anemic the mild rays are absorbed by it to a less extent than the strong ones. The procedure is indicated especially for radiation of malignant growths covered with skin and other soft parts accessible to injections of adrenalin.

Intravenous Injection of Pneumococcus Serum.—Beltz says of the Römer serum that theoretically it fulfills all requirements. It is polyvalent in the double sense, being a mixture of immune sera of various animals and therefore able to combine with the most varied complements, while it is specific to all known strains of pneumococcus. Naturally it would possess no specific power against pneumonia due to other than the Fraenkel diplococcus. From the viewpoint of practice testimony as to its clinical efficacy varies widely. If given toward the critical period a positive result is open to dispute, hence the remedy must be given by the third day in order to get a line as to a specific clinical result. The author has used it intravenously at about the third day in twenty-five cases. A few injections were made before and a few after the third day. The age of patients varied widely. It is significant that the two who died were between 50 and 60 years old. No data are given as to their cases. The author never saw the serum modify the course of the disease. He certainly would not inject the serum as a routine procedure early in the disease, especially with any hope of aborting the latter, for his experience would not justify any such procedure.

Industrial Affections of the Skin.—Herxheimer under this head enumerates no less than twenty-four etiological kinds of eczema due to the most varied irritants. The term dermatitis is not employed. The seventy-four varieties are associated with that number of callings, the occupation serving as a basis for classification. The first one listed is "cement itch"; next comes "baker's itch," then "washerwoman's itch," terms in use by the public. Wool and cotton spinners are next mentioned, their dermatitis being set up by irritating oils, which also set up eruptions with other occupations. The great majority of the lesions are naturally due to irritating chemicals of the most varied description in connection with the industrial arts. No less than twelve varieties of exotic wood are mentioned as being able to cause lesions in cabinet makers, turners, and other woodworkers. Next in frequency to eczema comes acne, the chief form of which is that due to chlorine, which is cognate with bromide and iodide acne. Rosacea is common enough in cabmen, cooks, etc., to be called a professional affection, and this is true of the chilblains of gardeners and others similarly exposed. Caustic burns and sores in various localities menace certain workmen, and these, as well as calloused surfaces, have received considerable expert consideration and are useful in identifications. In this connection should be mentioned boils and pustules. In addition to conditions due solely to certain irritants, certain workers are more exposed to definite diseases than others, so that occupation throws light on diagnosis. The wool sorter's anthrax, hostler's glanders, etc., readily suggest themselves here, but so should also the syphilis of glass blowers and smallpox of feather bed renovators. Prolonged irritation of the skin also leads often to the development of industrial cancer.

Contribution of the Study of Teratomata of the Ovaries.—M. Savarese reports a case of teratoma of the ovary, and presents the histories of eighty published cases. These tumors are relatively rare and occur in young women or girls; they differ from the other ovarian tumors in the youth of the patients, and in the occurrence of pain, amenorrhea, and the signs of malignancy. There is generally a pronounced distention of the abdomen from ascitic fluid. While these tumors are similar to dermoids in their genesis they differ from the latter in anatomical characteristics and clinical history. They are formed from all three layers of the blastoderm and are often cystic. One of their special characteristics is the large number of metastases to the omentum, and parietal and visceral peritoneum, consisting of small, white nodules of myxomatous or gliomatous tissues, unique in character. There are known transition forms between the teratomata and the dermoid cysts. The former are malignant on account of the rapid proliferation of their elements and their rapid development, as well as the tendency to degenerate into sarcoma or carcinoma. The diagnosis is difficult before operation, the early performance of which, according to Savarese, is the only advisable treatment.—*Folia Gynecologica.*

Insurance Medicine.

Prolongation of Life.—Rahts says that simple mortality statistics calculated as the number of deaths per 1,000 individuals may be very misleading when used in comparing various social groups. The mortality of the different ages differs so much as to affect the total mortality of a group when compared with another group of a different average age for its individuals. To judge duration of life properly, mortality must be calculated for every division of age, so that groups of the same average can be directly compared. If a single value is asked for, then it may best be calculated as the average duration of life from the mortality statistics of all the ages. Becker's statistics for Germany give the average duration of life in the seventies of the last century among males as 35.58 years, in the eighties 37.17, and in the nineties 40.56. The corresponding figures for the female sex run as follows: 38.45, 40.25, and 43.07. It is apparent therefore that the average duration of life in Germany has been increased by 14 per cent. in the thirty last years of the past century. This increase has come about by the diminution of mortality among the young and the very old. No change in the duration of life took place so far as the average age 45-46 is concerned. The typical "high age" has been reckoned as that in which the greatest number of deaths took place; this age was 71 years in the seventies, and 72 in the nineties.

However, Germany still remains behind several other nationalities of Europe, so far as duration of life is concerned. In Sweden, the average duration for the male sex is 50.04 and for the female 53.63 years; that is, almost ten years higher than in Germany. France and England also compare favorably with Germany, while Austria and Italy have a lower average duration of life. In all countries the female sex seems to have a higher average duration. Germany's lower showing is due to the high infant mortality as compared with other countries. Later statistics would probably show better figures for Germany because the problem of preservation of infant lives has been only lately given much attention in Germany. Of course, the increase in the average duration of life means an economic advantage to the nation that can only be measured by millions of dollars.

Somewhat different light is thrown upon statistics when the "expectation of life" at any age is studied. Figures show that such expectation is lowest in infancy and rapidly rises to its maximum at the age of 12 or 13 years. In the male sex the expectation of life is somewhat higher at this age because girls seem to be more liable to disease in school ages. The expectation of life then drops again until the age of 22 years is reached, then remains almost constant till 27 years, and finally gradually declines after this age. The drop in the curve after the maximum has been reached was very puzzling until lately, when separate causes of mortality began to be studied. It is now evident that this drop is due to the incidence of tuberculosis, both the drop in the curve and this disease being equally marked in the male sex at these ages. When tuberculosis is excluded the diminution in the expectation of life after the maximum has been reached becomes very gradual and about the same for both sexes.—*Zeitschrift für die Gesammte Versicherungs-Wissenschaft*, Vol. XI, No. 4.

Relationship of Tuberculosis to Accident and Injury.—W. Cecil Bosanquet states that this subject has acquired considerable importance within recent years in view of the enactment of employers' liability and workmen's compensation laws. The important facts to be considered in this connection are the possibility (1) that an accident or other injury may be the means by which tubercle bacilli are introduced into a person; or (2) that the injury may cause a weakening of natural resistance to the bacillus and thus permit it to establish itself when it would not otherwise have done so, or may lead to dissemination of the bacilli, thus giving rise either to a new focus of tuberculosis or to extension of one already existing. There are certain peculiarities about the tubercle bacillus which render the problem of the relationship between an injury and a subsequent tuberculous infection specially difficult to determine. In the first place the microorganism is fairly ubiquitous. Secondly the tubercle bacillus is a slowly growing organism in the majority of instances, so that symptoms of disease do not arise until some considerable period of time has elapsed after its actual introduction into the body or its establishment in some new focus. Accidental injury may cause a direct infection with tubercle bacilli, as in the case of the nurse who cut herself with a fragment of a broken spittoon which had contained tuberculous sputum. Butchers are liable to inoculation from cutting up infected cattle. The condition known as "anatomical tubercle" is a form of slowly developing verrucose tuberculosis of the skin which at one time was not uncommonly found among pathologists. It may be alleged that injury may cause the extension of an existing tuberculosis owing to a weakened resistance or to the dissemination of bacilli. Tuberculous disease of the joints should be considered in a class by itself. There is a considerable mass of evidence that in some way or other injury does lead to tuberculous arthritis; and if the occurrence of the accident is clearly established and it is followed at a reasonable interval by the tuberculosis one may accept the causal connection as probable. As to what constitutes a reasonable period of time opinions may differ, but it seems unlikely that symptoms would be delayed for more than three months. Also one must look for some sign that recovery has never been perfect—some persistence of pain or stiffness in the joint in the interval. Cases have been reported of pulmonary tuberculosis resulting from severe traumatism to the thorax, but in these cases there was probably a latent tuberculosis before the accident which served to quicken into activity the disease process. If the onset of a case of pulmonary disease were attributed to an injury one would be obliged to regard the assumption with grave doubt, since the sequence is undoubtedly rare and its very existence may be doubted. It is well established that injury may cause aggravation of an existing tuberculosis. It is only when the injury affects the tuberculous part directly that one can admit without scruple that subsequent increase of the disease is due to it. Before it could be admitted that an accident had aggravated an existing focus of tuberculosis situated at a distance from the part affected by the injury it would in any case be necessary to show that it was of such gravity as to produce a clear deterioration of general health.—*The Lancet*, January 13, 1912.

Apoplexy and Accident Insurance.—Procházka says that the real cause of an apoplectic stroke is either a disease of the arteries, resulting in a cerebral hemorrhage, or a disease of the heart, resulting in a cerebral embolism. In either case some accident may be the exciting cause, or at least play a significant rôle in the occurrence. In cerebral hemorrhage the breaking of the weakened vessel may be caused by undue exertion, by abrupt change in temperature of the body, by the rise of blood pressure following fright. Of course, concussion of the skull and brain may have a similar effect. Cerebral embolism may follow injury involving the thorax, any psychic excitement or physical strain leading to overactivity of the heart, etc. Any of these occurrences may be looked upon as determining the onset of an apoplectic stroke, and, therefore, they must be considered in all claims for indemnity by persons insured against injuries and accidents.—*Medizinische Blätter*, November 4, 1911.

Book Reviews.

Ueber Neurorezidive nach Salvarsan- und nach Quecksilberbehandlung. Ein Beitrag zur Lehre von der Fruhsyphilis des Gehirns. Von Dr. J. Benario. Mit einem Vorwort von Wirkl. Geheimen Rat P. Ehrlich. Mit 1 Tafel und 5 Figuren im Text. Price 6 marks. Munchen: J. F. Lehmann's Verlag, 1911.

Benario has collected all the published and many unpublished cases of the involvement of cerebral nerves or other parts of the nervous system after administration of salvarsan, and has compared their frequency with the frequency of similar lesions after the use of mercury. He concludes that these so-called "neurorelapses" are syphilitic in origin and are not due to arsenical poisoning; that they are a sign of insufficient treatment of the existing syphilis, and that their number must steadily diminish since the proper dosage of salvarsan has been determined. His evidence certainly seems to bear out the validity of his conclusions, and his monograph should be carefully perused by all physicians who have used or contemplate the use of Ehrlich's salvarsan in the treatment of syphilis.

The Parasitic Amœbæ of Man. By Charles F. Craig, M.D., Captain Medical Corps, United States Army. From the Bacteriological Laboratory of the Army Medical School, Washington, D. C., and the Rockefeller Institute for Medical Research, New York City. Price $2.50. Philadelphia and London: J. B. Lippincott Company, 1911.

The great importance of amebic infections has of late been pretty generally recognized, and they are so generally distributed throughout our country, especially in our tropical possessions, that almost any practitioner is liable to meet a case at any time. This monograph, which is the first on the subject that has appeared in English, gives in detail the work accomplished by numerous students of the parasitic ameba, together with descriptions of the species, especially as regards morphology, life cycle, methods of differentiation, and relation to disease. For several years Captain Craig has had unusual facilities for the study of his subject and he has made excellent use of his opportunities. The major portion of the work is based upon personal observations at the bedside, upon the autopsy table, and through the microscope, thus assuring an interest and value impossible in a compilation or a review of the literature. The descriptions are minute and exact and the illustrations are most satisfactory. His emphasis on the fact that a very large percentage of men in certain sections of the country harbor a non-pathogenic ameba in their feces is exceedingly well timed and makes one wonder how much value can be attached to many of the case reports in which the diagnosis was made simply on the finding of an ameba in the stool. This volume should prove of great value to practitioners as well as to laboratory workers despite the fact that treatment is not touched upon. There is appended a very complete bibliography.

A Manual of Materia Medica for Medical Students. By E. Quin Thornton, M.D., Assistant Professor of Materia Medica in the Jefferson Medical College, Philadelphia. Price $3.50. Philadelphia and New York: Lea & Febiger, 1911.

This book is designed for the medical student and in many respects it meets his requirements most admirably. It is not too discursive, it does not trench too much on the domain of therapeutics, and it presents the main facts of materia medica with sufficient detail. The first part deals with posology, prescription writing, Latin essentials in prescription writing, incompatibility, and weights and measures. Part II, the most important section of the book, is devoted to the discussion of the drugs and preparations official in the U.S.P. Attention is given to the English and Latin names, synonyms, sources, properties, incompatibilities, constituents, administration, dosage, poisonous effects, and antidotes. Part III gives a list of the pharmacopœial preparations. The only adverse criticism we have to make is on the quality of the Latin and the uncertainty of the dosage. The section on Latin essentials in prescription writing is the weakest part of the whole book. It is evident that the author has not the same first-hand knowledge of Latin that he has of materia medica. On page 44 *sulphatis* is said to be feminine, and on page 45 it is given as masculine; *sodii* is said to be a feminine noun; *fiat* is said to be a transitive verb; *recepti* is given as the perfect of recipio; *dat* is given as the present subjunctive of do; "*capiat cochleare unam parvam ex paulo aqua*" is an atrocity which makes a classical student shudder. The whole of this section is very much like one in an older and more elementary work by the same author. With regard to the dosage, this is inconsistent, and in a work designed for medical students such inconsistency should be avoided. Thus, the dose of liquor ammonii acetatis is given as 1 to 4 drams and also as 1 to 8 drams; that of tincture of aconite as 3 to 10 minims and also as 5 to 20 minims; of Tully's powder as 1 to 5 grains and also as 5 to 10 grains; of blue mass as 3 to 10 grains and also as 2 to 20 grains; of extract of nux vomica as 1/6 to ½ grain, and also as 1/6 to 1 grain; of Basham's mixture as 1 to 4 drams and also as 2 to 8 drams; of amyl nitrite as 3 minims and also as 3 to 10 minims. It will be noticed that in some cases these differences are quite considerable. Among other points that should be corrected in another edition are the statements that "gallic acid is an inorganic acid" and that "sodium bromide is made by double decomposition between potassium carbonate and ferrous bromide."

Syphilis, from the Modern Standpoint. By James McIntosh, M.D. (Aberd.), Grocers' Rearch Scholar, and Paul Fildes, M.B., B.C. (Cantab.), Assistant Bacteriologist to the London Hospital. Illustrated. New York: Longmans, Green & Co., 1911.

The discovery of the *Treponema pallidum*, the use of the deviation of complement reaction in the diagnosis of syphilis, and the appearance of salvarsan as the sovereign antisyphilitic remedy have quite revolutionized our knowledge of syphilis and have rendered obsolete the classic treatises of the disease. The manual before us collects all the remarkable advances in the domain of syphilis and presents that disease as other infections have been presented in bacteriological textbooks. Yet, while the laboratory diagnosis and the pathology of syphilis are fully treated, many clinical features of the disease are touched upon, so that the volume is of interest to the practical physician as well as to the immunologist. The identification of the *Treponema pallidum*, the technique and interpretation of the Wasermann reaction, the value of salvarsan are the subjects especially fully treated. The information, too, is not a mere compilation of literature, but an abstract of experience of two men occupied with the subject matter of the book. This makes this small manual (a little over 200 pages) one of the most valuable among the numerous works on syphilis that have appeared lately. We heartily recommend the work to physicians looking for an authoritative statement of the new lore in this disease.

Serum Diagnosis of Syphilis and the Butyric Acid Test for Syphilis. By Hideo Noguchi, M.D., M.Sc., Associate Member of the Rockefeller Institute for Medical Research, New York. Fourteen illustrations. Second Edition. Price $2.50. Philadelphia and London: J. B. Lippincott Company, 1911.

Dr. Noguchi's method of the serum diagnosis of syphilis has now been tested in over 10,000 cases of syphilitic, parasyphilitic, and other disease. It has been shown to be as accurate as the original Wassermann method, and somewhat simpler. In the new edition of his manual Noguchi gives the technique of his method and Wassermann's as well, and includes, in addition, much information valuable in selecting and testing suitable antigen for the performance of the reactions. He also gives many new data supporting the reliability of his butyric acid test for syphilis. The book is clearly written, the directions are ample and well illustrated, and the monograph, accordingly, should prove of great value to the immunologist occupied with the methods of diagnosing syphilis.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles * * * by Leading Members of the Medical Profession Throughout the World. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, U. S. A. Volume III: Twenty-first Series. Price $2.00. Philadelphia and London: J. B. Lippincott Company, 1911.

The present volume of this well-known quarterly shows as varied and as entertaining contents as any of its predecessors. Therapeutics, Medicine, Pediatrics, Neurology, Surgery, Diseases of the Ear, Obstetrics, Ophthalmology, and Economics of Medicine, one or more articles appear under these various headings. Of them, Heart Therapeutics, by James J. Walsh, is an entertaining study of the influence of rest and suggestion upon "cardiac" patients; Relationship Between Gastric and Urinary Acidity is discussed by Thomas R. Brown; I. W. Hunter writes on Venereal Diseases in Children; Thomas F. Reilly gives many hints valuable to the beginner in a paper on the Successful Practice of Medicine, etc., etc. In all, the volume contains twenty-two well written articles in the various departments of medicine named above.

Einfuhrung in die Physiologie, Pathologie, und Hygiene der menschlichen Stimme. Von Dr. Ernst Barth, mit 200 Abbildungen und 2 farbigen Tafeln. Leipzig: Verlag von Georg Thieme, 1911.

With characteristic Teutonic thoroughness this book covers the subject of the human voice. It opens with a chapter on acoustics and tone production, followed by one on the breathing apparatus, with special attention to the muscles and vocal accessories, as pharynx, palate, nasal organ, etc. Then comes a series of interesting chapters on the various types of breathing, origin of the voice in the larynx, proper methods of examining the larynx, the register of the voice and its ontogenetic development, origin of vowels and consonants, etc., etc. Under the pathology of the voice the changes produced by some dozen different diseased conditions are enumerated, and the book closes with a part on the hygiene of the voice. The book is complete, orthodox, and well subdivided.

Diseases of the Ear, Nose, and Throat, for the Family Physician and the Undergraduate Medical Student. By Henry Ottridge Reik, M.D., Associate in Ophthalmology and Otology in Johns Hopkins University, and Surgeon in the Baltimore Eye, Ear, and Throat Hospital, Baltimore, Md.; assisted by A. J. Neilson Reik, M.D., Surgeon in the Baltimore Eye, Ear, and Throat Hospital, Baltimore, Md. With 81 illustrations in the text and two colored inserts. Price $4.00. New York and London: D. Appleton & Co., 1911.

This is an excellent book and will well fill the purpose for which it was intended. The author does not encroach upon the territory of the specialist and yet he is not too elementary in his discussions of the diagnosis and treatment of ear, nose, and throat diseases. His description of the influence of the tonsils and adenoids on the general health and on the hearing is eminently clear, and his statement regarding the inadvisability of one not especially trained undertaking the operation of tonsillectomy is sound. The chapters on bronchoscopy, epistaxis, asthma, epilepsy, and carcinoma of the tongue bring these subjects fully up to date and make the book a useful guide for the general practitioner.

Applied Anatomy and Oral Surgery, for Dental Students. By Robert H. Ivy, M.D., D.D.S., Assistant Oral Surgeon at the Philadelphia General Hospital; Assistant Surgeon Out-Patient Department University Hospital, Philadelphia. Illustrated. Price $1.50. Philadelpha and London: W. B. Saunders Co., 1911.

This book represents the progressive movement in dentistry, which includes much more than a mere knowledge of dental pathology and mechanics. There are chapters on the circulation and composition of the blood, inflammation, contusions, and wounds, surgical fever, anesthesia, and general instructions as to sterilization of instruments and preparation of patients for operation. The chapter on diseases of the maxillary sinus is well done, as is also that on fractures of the jaw. Review questions are given at the end of each chapter and are designed to aid the student in going over the work a second time. The book is of distinct value to dental students, and will prove of help to medical men who are interested in the surgery of the head and neck.

Lippincott's New Medical Dictionary. A Vocabulary of the Terms Used in Medicine, Dentistry, Veterinary Medicine, and the Allied Sciences, with their Pronunciation, Etymology, and Signification, including much Collateral Information of a Descriptive and Encyclopedic Character. By Henry W. Cattell, A.M., M.D., Editor of International Clinics, Fellow of the College of Physicians of Philadelphia, etc. Freely Illustrated with Figures in the Text. Second Edition. Philadelphia and London: J. B. Lippincott Company, 1911.

In this second edition of Lippincott's Dictionary there have been over 5,000 additions and changes made in the text, the editor states, about 500 new words having been inserted. Much ingenuity has been expended by the Editor in making these 5,000 additions, for the size of the book has not been increased by even one page and every letter begins and ends on the same pages as in the first edition. The illustrations have apparently been increased in number, thought not always judiciously; we find, for example, on page 483, alongside of the same caricature of Koch that marred the first edition (though it is here smaller), an equally libellous representation of Theodore Kocher. All the excellent features of the first edition, such as the use of lower-case titles, illustrated medical bibliographies, illustrations of medicinal plants, etc., have been retained in this revision. The publishers claim that this was the first medical dictionary to contain medical and veterinary terms, but we think this must be an error, for we remember to have seen some medical terms in one of the earliest editions of Dunglison's Dictionary, and this feature has been copied more or less successfully by all medical dictionaries since that time. Most of the dictionaries have also contained some veterinary terms. But even disallowing these claims of the publishers there are good features enough in this scholarly work to recommend it. The chief fault, and one that is inherent in the arrangement of the titles, is the difficulty offered to one who looks for a definition by the lack of alphabetical sequence in many cases.

Das Erkenntnisproblem und seine kritische Lösung. Von Berthold Kern. Zweite erweiterte Auflage. Price 5 marks. Berlin: Verlag von August Hirschwald, 1911.

This monograph reviews the theories of knowledge that have been put forth by various thinkers and then presents the author's original theory of the matter, which seems to be based almost entirely on Kant's critical study of the human mind and its processes. It should prove of interest to any physician who likes to delve in metaphysical matters.

The Origin of Life. Being an account of Experiments with Certain Superheated Saline Solutions in Hermetically Sealed Vessels. By H. Charlton Bastian, M.D., F.R.S. Emeritus Professor of the Principles and Practice of Medicine, University College, London. With ten plates, containing numerous illustrations from photomicrographs. Price $1.50. New York and London: The Knickerbocker Press, G. P. Putnam's Sons, 1911.

For several reasons this is an interesting work. In the first place, although its venerable author is one of the oldest and best known of the Fellows of the Royal Society, that society did not consider this memoir suitable for its acceptance. This, of course, is not necessarily derogatory either to the author or to his thesis, for the same society at an earlier date rejected Joule's paper on the "Mechanical Equivalent of Heat," which subsequently proved such an important contribution to the doctrine of the correlation of the physical forces enunciated by Grove. Next, although Pasteur's work has been very generally accepted, and with it the belief that life comes from life and from life only; still it has not been (and naturally cannot be) proved that life never can and never will appear spontaneously. This book contains an account of Bastian's experiments; any competent scientist can duplicate them, and if such repetition should lead to similar results our present beliefs as to life and its origin will have to be modified. Life originated once; why may it not originate again? The old controversy, represented by Pasteur, Tyndall, and Lister on one side, and by Haeckel, Pouchet, Hughes, Bennett, and Bastian on the other side, may still prove to be alive. In the meantime all interested in these biological problems will feel grateful that the Royal Society rejected this work; for had it accepted these papers they would have been buried in a volume of transactions, and so have been inaccessible to the world at large.

The Mechanism of Life. By Dr. Stephen Leduc, Professor at l'Ecole de Médecine de Nantes. Translated by W. Deane Butcher, formerly President of the Röntgen Society and of the Electro-Therapeutical Section of the Royal Society of Medicine. Price, $2.00. New York: Rebman Company.

It is curious that this book should appear at the same time as Bastian's work on "The Origin of Life." They both deal with the same biological problem, and they were both practically branded as scientific heresy by the "powers that be." Bastian's memoirs were "not considered suitable for acceptance by the Royal Society"; and Leduc's "Théorie Physio-Chimique de la Vie et Générations Spontanées" was excluded by the Académie des Sciences from its *Comptes Rendus*. Every man who thinks at all about the great problems of life will welcome this volume, which is as interesting as it is important. Particularly noticeable are the clearly expressed views of the author, and the admirable definitions and descriptions. There is never any doubt as to his meaning. The language is so clear and certain that it is hard to believe that we are reading a translation. The subjects discussed are: Life and living beings; solutions; electrolytic solutions; colloids; diffusion and osmosis; periodicity; cohesion and crystallization; karyokinesis; energetics; synthetic biology; osmotic growth; the phenomena of life and osmotic productions; and evolution and spontaneous generation. This book and the companion volume of Bastian's are among the most important works of the year.

HANDBUCH DER ALLGEMEINEN UND SPEZIELLEN ARZNEIVERORDNUNGSLEHRE. Auf Grundlage des deutschen Arzneibuches 5. Aufgabe und der neuesten auslandischen Pharmakopoën. Bearbeitet von Dr. C. A. EWALD, Geh. Med.-Rat, o. Honorarprofessor an der konigl. Universitat, dirigieriender Arzt am Augusta-Hospital zu Berlin; und Dr. A. HEFFTER, Geh. Med.-Rat, o. Professor und Direktor des pharmakologischen Instituts an der königl. Universitat zu Berlin. Mit einem Beitrag von Professor Dr. E. FRIEDBERGER. Vierzehnte ganzlich umgearbeitete Auflage. Price 18 marks. Berlin: Verlag von August Hirschwald, 1911.

THIS is the fourteenth edition of the well-known and venerable textbook on materia medica originally written by Posner and Simon but now revived by Ewald and Heffter. It is based upon the fifth edition of the German pharmacopœia and the pharmacopœias of other countries. One need hardly comment on the thoroughness of this work, its scientific accuracy, and the readiness with which it may be referred to, thanks to an excellent index. It combines the qualities of a textbook of materia medica with those of a formulary, containing incorporated in the text a total of 1,643 prescriptions. He who would keep abreast of what is offered by the pharmacopœias of the Old World can not afford to get along without this volume.

DIE DIVERTIKEL UND DILATATIONEN DER SPEISERÖHRE. Von Dr. HUGO STARCK. M. 2.40. Halle: Carl Marhold Verlagsbuchhandlung, 1911.

WITH regard to dilatation of the esophagus, which is so much more frequent than diverticula, Starck has the following to say: A diet list suitable for all cases of esophageal dilatation cannot be given. For the permeability of the cardia varies in different patients for the same food. The one case permits fluids and semisolids to pass more readily, the other solid, firm substances. Starck had a patient who wanted particularly heavy food, lentils and peas. These disappeared quickly into the stomach, whereas soft and fluid food remained above for a long time. All our endeavors must tend to remove the stenosis at the cardia. Von Mikulicz was probably the first to attempt to dilate the cardia by operation through the stomach. This can be accomplished by digital divulsion or by hyperextension by means of a dilator. Lately this divulsion has been performed by dilators introduced through the mouth. We must, of course, be able to enter the cardia. If we accomplish this, success is assured. Dilatation is done about twice weekly and often the patient is able to swallow after the first treatment. Sometimes this occurs only afer several treatments. In one of Starck's cases the esophagus held no more residual food from the day of the first dilatation. With the dilating instrument we desire to overstretch the muscular ring, without at the same time injuring the elastic mucous membrane. If a fissure of the mucous membrane occurs we must wait some time with our attempts at dilatation. What is the success of our dilatation? The wall of the esophagus never returns to normal, a dilatation remains until death, but the cardia allows food to pass, no food remains (in the moderate and fusiform dilatations), or the food remnants are scanty (sacculated or bottle-shaped dilatations). The esophagus can contract to a degree and the signs of irritation disappear. Recurrences occur, but can be cured by renewed dilatation. We have in this method a means to cure the patient relatively and prevent his starvation.

THE MECHANICAL FACTORS OF DIGESTION. By WALTER B. CANNON, M.D., Professor of Physiology, Harvard University. London and New York: Longmans, Green & Co., 1911.

THIS is the first volume of a projected series of International Monographs edited by Drs. Leonard Hill and William Buloch. In it Cannon embodies his well-known researches with regard to the processes of digestion. According to Cannon the presence of peristaltic waves in the right half of the stomach and their absence from the left half indicate two separate parts of the stomach. The evidence now before us shows that these two parts have distinct functions. The left half is a reservoir in which the food is not mixed with the gastric secretion and from which the contents are slowly pressed out into the active right half. The peristaltic waves coursing over the right half mix the food with the gastric juice, expose it to the mucosa of the vestibule for absorption and for the continuance of gastric secretion, churn the unbroken particles of food until they are triturated, and finally expel the chyme into the duodenum. The pylorus is tonically closed when food is ingesed and remains closed against recurring pressure. The appearance of acid at the pylorus causes the sphincter to relax. The pressing peristaltic waves now force some of the acid chyme into the duodenum. The acid in the duodenum at once tightens the sphincter against further exit. The same acid also stimulates the flow of alkaline pancreatic juice. Since no inorganic acid is normally present beyond the first centimeters of the small intestine and since the acid reaction of the contents in this uppermost region is replaced throughout the rest of the small intestine by practically a neutral reaction, the acid chyme must be neutralized soon after its emergence from the stomach. As neutralization proceeds the stimulus closing the pylorus is weakened; now the acid in the stomach is able to relax the sphincter. Again the acid food goes forth and immediately closes the passage behind until the duodenal processes have undergone their slower change. And thus, repeatedly, until the stomach is empty. The book is herewith warmly recommended.

DIE METHODEN DER UNTERSUCHUNG DES MAGENS UND IHRE DIAGNOSTISCHE VERWERTUNG. Von Dr. EMIL SCHUTZ, Privatdozent an der Universitat Wien. Mit 80 Textabbildungen. Price $2.75. Vienna and Berlin: Urban & Schwarzenberg; New York: Rebman Company, 1911.

NUMEROUS isolated additions to the diagnosis of gastric diseases have appeared in the last few years in the periodical medical literature, but no book has been published lately that attempted to separate the grain from the chaff in these publications and to gather the new knowledge into a systematized whole. Schütz's book attempts to do just that, entering into the various methods proposed and giving the author's valuation of them. Especially to be mentioned is the author's careful presentation of the results of palpation of the gastric region, according to the technique elaborated by Glenard, Obratzow, and lately Hausmann. The more spectacular and special methods, such as gastrodiaphany, *x*-rays, etc., have for a time crowded simple palpation into the background, but signs are not failing to show that this method, of which every careful physician can avail himself without laboratory and hospital apparatus, is fast regaining its proper place in diagnosis of abdominal conditions. Schütz's careful presentation of palpatory findings is typical of the whole book: it leaves nothing desired in the way of presenting the diagnostic methods and of interpreting the results obtained. We know no better book on the diagnosis of gastric disease for the use of the internist.

MÉMOIRES RÉDIGÉS EN L'HONNEUR DU PROFESSEUR RAPHAËL LÉPINE À l'occasion de sa retraite. Par ses élèves et ses amis. Paris: Librairie Félix Alcan, 1911.

THIS book, which is the October issue of the *Revue de Médecine*, is a volume of several hundred pages containing over one hundred short papers by the pupils and friends of Professor Lépine. Most of the articles consist of a few remarks on some clinical or pathological subject, and their only *raison d'être* is the apparent desire of the editors to include as many friends of Dr. Lépine as possible among the contributors. More pretentious are papers on lumbar puncture in uremia, hemiplegia iin pneumonia, acetone in diabetes, hemolytic icterus in cirrhosis of the liver, cysts of the kidney, etc., by various authors. The volume is a fair reflection of the French medical thought, and physicians should find some one thing or another of interest in its multiform table of contents.

DIAGNOSE UND FEHLDIAGNOSE VON GEHIRNERKRANKUNGEN AUS DER PAPILLE NERVI OPTICI. Von Prof. Dr. Fr. SALZER, München. Mit 29 Abbildungen auf 2 farbigen Tafeln. Price 1.50 marks. München: J. F. Lehmann's Verlag, 1911.

THIS is a brochure of sixteen pages in which the author deseribes the appearances of the optic nerve papilla in diseases of the brain, as well as normal variations of the retina and optic disc, that may lead to confusion. It is illustrated by two very good colored plates picturing a number of normal and pathological appearances of the fundus of the eye.

HEART SOUNDS AND MURMURS. By E. M. BROCKBANK, M.D. (Vict.), F.R.C.P.; Senior Hon. Assistant Physician Royal Infirmary, Manchester. Price 2/6. London: H. K. Lewis, 1911.

IN this small volume the author has attempted to put into convenient form the elements of cardiac auscultation for the use of students. As a whole it is well done, except that the reader is apt to understand him to say that a murmur *per se* means a valve lesion, a rather dangerous doctrine to instill into a medical student. Also he persists in his theory of the causation of the presystolic murumr of mitral stenosis in spite of the fact that this has been pretty thoroughly disproved by the use of the electrocardiograph and by the experimental work of Hirschfelder. The book will hardly find a large field in this country

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting Held January 4, 1912

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

THIS meeting was held under the auspices of the New York Academy of Medicine Committee on Public Health, Hospitals, and Budget. The subject of the evening was "Occupational Diseases."

Report of the Committee on Medical Expert Testimony.—Dr. JOHN H. HUDDLESTON read this report. It was moved, seconded, and unanimously carried that this report be accepted. It read as follows:

"The Committee on Medical Expert Testimony has had a number of conferences with the Committee of the New York Bar Association and has had also several meetings in which they have conferred upon the matters assigned to them. They have reached the following conclusions:

"1. That it would be advisable to favor the passage of the so-called Clearwater Bill or some modification of it. The modification which we have agreed upon to favor is that the Judges appoint a list of medical experts in each Judicial District. This list to include only the men who come up to the minimum standard of qualification for expertness prescribed by the resolutions which we submit here. This will make the Bill cover two definite and essential points. (*a*) That the medical expert be paid by or through the Court and not by the parties in whose behalf the expert testifies. (*b*) That the medical expert have certain definite minimum standard of qualification.

"2. The Committee ask that the Statement of the Evils of Expert Testimony as presented by Judge Clearwater be added to the report.

"3. The Committee recommends that the Council adopt and recommend to the Academy for adoption the following Resolutions: *Whereas*: Medical expert testimony is necessary and helpful to justice and ought to be effectively and freely used in the courts. And *whereas*: The methods of legal procedure in trials involving medical expert testimony are now inefficient, and fail to utilize effectively expert knowledge and skill. Therefore in order to promote an improvement in these conditions, this Committee asks the adoption of the following recommendations by the Council and Academy of Medicine.

"*As regards the legal side of the medical expert question we recommend*: (1) A freer use of appointments of commissions and of experts by the court. (2) That the medical expert should be paid by or through the court, and not by the party in whose behalf he testifies. (3) That the period of hospital or similar form of observation of persons the nature of whose troubles is under dispute be adopted as being the best method for securing impartial and accurate opinions; and we recommend the enactment in every State of laws favoring such method.

"*As regards the medical side of the question we recommend*: (4). That it be adopted as the opinion of the Council and Academy that it is inadvisable and objectionable for any physician to occupy the position of medical advisory counsel in open court and at the same time to act as expert witness in a medicolegal case. (5) That it be adopted as the opinion of the Council and Academy that the acceptance by a physician of a fee that is contingent upon the result of a medicolegal case is not in accordance with medical ethics, is derogatory to the good repute of the profession, and is injurious to the efficacy of expert testimony. (6) That the Academy adopt the following as a definite minimum standard of qualification for medical men giving expert testimony: 'That a physician should not be considered a medical, surgical, or special expert unless he is a graduate of a reputable medical college; has paid special attention for at least six years to the particular branch as to which he claims to be expert; has had opportunities of laboratory or clinical study or both in that branch for at least four years, and is a member of a general and of a special medical society in good standing.' (7) That the Academy recommend that other medical organizations adopt this or a similar minimum standard." Signed, Charles L. Dana, Edward D. Fisher, Bernard Sachs, Max G. Schlapp.

The Evils of Medical Expert Testimony.—Statement of the case by Judge Clearwater in a review. "(1) There are no satisfactory standards of expertness, and thus the testimony of charlatans is invited; (2) The character of the evidence often given by so-called experts is partisan and unreliable; (3) Trials are prolonged and their expense is increased on account of the number of witnesses; (4) The contradictory testimony of experts of apparently equal standing, having the same opportunities for acquiring knowledge of the facts, has a confusing effect upon juries; (5) Unprincipled self-styled experts are sometimes unscrupulously hired to support causes by specious and untruthful testimony; (6) Some Trial Judges are prone to permit incompetent so-called experts to testify to opinions predicated upon widely unrelated facts, and to express views which are but the speculative vagaries of ill-formed minds; (7) The expert must depend for compensation solely upon the litigant for whom he testifies; (8) The litigant who has the longest purse can produce the most imposing array of experts; (9) The Bench sometimes permits the Bar to treat the accomplished and modest expert with studied contempt; (10) Some Trial Judges are disposed to convert important trials into spectacular dramas which not infrequently descend to comedy and degenerate into farce, with the result that the administration of justice is degraded."

Acknowledge Treasurer's Services.—Dr. A. M. JACOBUS moved that a special vote of thanks be given for the very efficient and valuable services of Dr. Reginald R. Sayre, one of the most valuable treasurers the Academy had ever had. This was seconded and unanimously carried.

Appropriation for the Library.—It was moved, seconded, and carried that $5,000 be given for the use of the library.

Résumé of the Importance and Prevalence of Occupational Diseases.—Dr. W. GILMAN THOMPSON read this paper. (See page 201).

State Control of Occupational Diseases.—LEONARD W. HATCH, State Statistician of the New York State Department of Labor, read this paper by invitation. (See page 202).

Occupational Neuroses Due to Metallic Poisons.—Dr. M. ALLEN STARR read this paper. (See page 205).

Occupational Paralyses and Atrophies.—Dr. CHARLES L. DANA read this paper. (To be published later.)

Occupational Diseases of the Skin.—Dr. JOHN A. FORDYCE read this paper. (See page 207).

Dr. JAMES ALEXANDER MILLER said there were but two aspects of the question before them that he would like to refer to briefly. One was the fact that a great many of the occupational diseases reported to-day were based on information that was out of date, a knowledge that had been gained from information that had been passed on to generation after generation, and to which practically nothing had been added. Now the opportunity was given the medical profession to add much to the knowledge of this subject by scientific investigations, and especially in regard to the respiratory diseases which resulted from dust, fumes, gases, and so forth, and their relation to the causation of tuberculosis. His attention was called to this by two investigations he had been called upon to undertake. One was in connection with the subway conditions, where it was stated that the workers in the subway were very much subjected

to respiratory diseases because of the inhalation of iron particles. Dr. Soper, some time ago, undertook an investigation of this, and he had this idea in mind. It was stated that one ton of steel and iron per mile per year was given out in the form of dust, and the question arose what effect this had on the employees. Examinations of the employees found that they in fact had no impairment in health because of their occupation in the subway; many gained in weight, in the common parlance they gained "subway fat." Many gained in their general health while engaged in the subway. This seemed to disprove the statement that the inhalation of iron dust had any deleterious effect upon health. It was stated that printers had a high rate of mortality from tuberculosis because of their occupation. Investigations of Typographical Union No. VI—200 were examined—showed a large percentage among them of tuberculosis, something like 17 per cent. After very careful examination it was found that one-half of them had cured tuberculosis; they had had tuberculosis, left their employment, took care of themselves, returned to their trade, and had no relapse. The knowledge they gained enabled them to return to their trade and keep well. It would seem therefore that the habits of the printers rather than their occupation were at fault. Dr. Miller thought that there was needed a more careful study of the various problems regarding various employments and tuberculosis. In New York the Cloak Makers' Union was studying the health of its employees. In Chicago the Harvester Company and in Boston the department stores were doing the same thing. This would lead to very valuable information regarding the influence of occupations upon various diseases. From a scientific point of view a study of the effect of occupation upon employees should be undertaken by the medical profession: it should take the lead in this work, and in this the Committee on Public Health, Hospitals and Budget should play a very important part.

Dr. Frederic S. Lee said that they had been hearing of special conditions and reading about special diseases, but he wished to speak about some general conditions which produced some general physical states which in turn conduced to disease. He used lantern slides to illustrate his remarks. The first condition he referred to was the quality of the atmosphere which surrounded workmen, and he called attention to the work of Billings and others who had shown that the deleterious effects of atmospheres in closed rooms was not due to inspiration of organic substances which the expired air was supposed to contain; it was not due to the quantity of carbon dioxide, for the atmosphere in these closed rooms could contain from three to four per cent. of this gas without producing deleterious effects. But their work did show that the deleterious effects were connected with the temperature and the humidity of the air in these closed rooms. Any workman who labored in closed rooms with a high temperature and where the atmosphere was very humid suffered in various ways. Because of the fact that the body could not cool itself by evaporation of the perspiration, the body temperature rose. Dr. Lee said he had just received and read with much interest a report on humidity and ventilation among the cotton weavers in England; it was claimed that, especially in the coarse cotton weaving, it was necessary to have the rooms very humid and various artificial methods were in use to render the air moist, and this was to the detriment of the workmen. Lantern slides were shown of the effects of fatigue. Fatigue among workmen had increased very much during the past few years because of greater speed required of them in their work; because, too, of the monotony of their work and other conditions which conduced to fatigue. Fatigue certainly increased one's susceptibility to infectious diseases in that it diminished the quantity of antibodies of an individual. Slides were shown to illustrate the relation of fatigue to the occurrence of accidents. There were two parts of the day, one in the morning and the other in the afternoon, when fatigue was the greatest and when accidents most frequently occurred.

Dr. C. T. Graham-Rogers, Medical Inspector of Factories, N. Y. State Labor Department, New York City, (by invitation) said he would speak more of opinions he had formed as the result of medical inspection of factories in the State of New York. In studying the causes of industrial diseases there were three factors to be considered, the factory, the worker, and the housing. Mercury was not used as claimed in the manufacture of silk hats, but it was used in the making of silk hats; the air in the fur-cutting room of such factories contained 2.6 milligrams of mercury per cubic meter. With regard to printing, linotype composing rooms contained no lead in the air as claimed by many. In electrotyping there were found in the rooms fine particles of dust with lead and arsenic contained therein. Wall paper to-day contained no arsenic. In the manufacture of artificial flowers wood alcohol was used, and there was aniline to be found in the dust, but no arsenic. In brass casting there were 75.2 grams of dust per million liters of air, and in it 55.4 grams of silica, also traces of zinc and copper. In sugar houses there were noted high temperature and humidity. In the manufacture of pearl buttons silica was found in the atmosphere; in print works, aniline and carbon-dioxide gas; in wire works, sulphuric acid (52.2 milligrams per million liters), iron (100 milligrams per million liters of air), and dust (88 milligrams per million liters); in the manufacture of gas mantles and garments carbon monoxide was found in the atmosphere. In the manufacture of matches phosphorus, 1.1 milligram per cubic centimeter, was noted. In mica goods 0.1 gram per cubic centimeter was found. He said that hours could be spent in the discussion of the diseases of occupation, and still very little ground be covered; so that in the short time allowed him it would be impossible to even more than emphasize important points of the divisions they might call industrial. For years the industries, and by that he meant manufacturing processes, had borne the burden as a direct cause of certain diseases, the accusation being based mainly upon mortality statistics. It was true that there was danger of poisoning or intoxication in certain industries, but every industry might be made safe by the application of safeguards. If the industry could not be made reasonably safe either by substitution of non-poisonous materials or proper appliances, it should be either prohibited or restricted. We were now in an era of prevention; our aim was to find the cause and remove it. It was not so long ago that all conditions of malaise were called malaria and ascribed to certain atmospheric conditions. If we desired to reduce diseases among the factory toilers, we should first analyze the process of manufacture, or conditions under which such processes were carried on, and determine the specific cause; then it would become very easy to supply the remedy through legal measures or otherwise. The study of occupational diseases was one of the first principles of hygiene, and was intimately associated with labor laws. Sir John Simon said "uncleanliness must be reckoned as the deadliest removable cause of disease." Dirt and disease were synonymous. The prevention of industrial diseases must be accomplished through cleanliness. Air made unclean through contamination by dust, fumes, gases, or vapors, or structural parts of buildings made unclean by dust and dirt, were the causes. Remove these causes, and the industry could no longer be blamed. The troubles then lay with the individual, and this became an educational as well as a public-health problem, as Dr. Richardson had very truly said. Uncleanliness, Dr. Graham-Rogers maintained, covered the whole field of sanitary law; it was the beginning and it was the end.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 28, 1911.

DR. FRANKLIN A. DORMAN, CHAIRMAN PRO TEM.

Omental Adhesions Following Operations, with Nausea for Two Years.—DR. LE ROY BROUN reported this case. A stenographer, twenty-seven years of age, was referred to him with the history of having had an operation for retroversion of the uterus, after which she had attacks of vomiting after each meal at intervals; sometimes this condition persisted for months. Her weight had fallen off from 160 to 130 pounds. She was admitted to the hospital on September 26, 1911, and kept under observation for a week, when an operation was determined on. The stomach and duodenum showed no evidence of abnormality. The stomach, however, was displaced downward and the transverse colon was pulled below the umbilicus by several dense adhesions of the omentum to the abdominal wall. No other abnormalities could be found. These adhesions were severed and the omentum was quilted and stitched to the abdominal wall above the umbilicus. The appendix was removed, although it showed no evidence of disease. After this the patient ceased to vomit, gained in weight, and was relieved of all her gastric pain. The omental adhesions had fixed the transverse colon in a vicious ptosis; this had pulled on the stomach and had also undoubtedly caused pressure through its mesentery and the superior mesenteric artery on the underlying duodenum, starting up the stomach disturbance. Dr. Broun said that since his attention had been called to omental adhesions and their influence on the transverse colon and the stomach, he had made it a uniform practice at the close of every operation to place the patient in the extreme Trendelenburg position and to give two quarts of salt solution by rectum. This would throw the transverse colon back into its normal position and prevent abnormal fixations.

Resection of Redundant Sigmoid.—DR. LE ROY BROUN said that in the preceding case they had symptoms resulting from an acquired ptosis as the result of adhesions, while in this case there was a defective development with the resulting pathological conditions and intercurring symptoms. The patient was an unmarried woman, twenty years of age, with all the symptoms of neurasthenia. The local condition was one of retroversion of the uterus and hemorrhoids. The uterus was replaced by shortening the round ligaments through a small transverse incision and the appendix was removed. The entire pelvis was occupied by a redundant sigmoid, which was much dilated and congested. The sigmoid was fastened to the abdominal wall, in the hope that some of the symptoms might be relieved. Resection was not done because the patient had not been consulted in the matter. Two and one-half months later she again entered the hospital and a resection of eight inches of redundant sigmoid was done. The attachment of the redundant sigmoid to the abdominal wall had improved her condition materially; the sigmoid was less distended and less congested. After resection of the sigmoid the transverse colon was suspended by its quilted omentum to the abdominal wall. The patient had made an uninterrupted recovery. Dr. Broun believed that such operations should only be done as a last resort, and then without any absolute assurance of relief from the symptoms. In those patients that they met with in the hospitals it was difficult to carry out any conservative treatment; they were forced back to work and could not rest or be subjected to long lines of medical treatment.

Squamous Epithelioma of the Cervix Associated with Tuberculous Peritonitis.—DR. LE ROY BROUN reported this case. The patient, thirty years of age, had been married twice. Her first husband lived seven years, and during this time she had two children, the first stillborn, the second born after a normal labor. Since the birth of her first child her health had not been good. Menstruation had been profuse and there was scarcely any interval between one period and another. She had been curetted twice, but not within the last four years. Her general condition was one of intense nervousness and anxiety. During the three years of her second marriage she was practically an invalid. The indication was that of radical operation for cancer, but the youth of the patient made them hesitate to take away all hope of maternity. Large sections were taken from the parts involved and sent to the laboratory for a report on frozen sections. The report returned was that they were free from cancer. On the basis of this report a high amputation of the cervix was done and the excised portion was examined in the regular way. The report was that the condition was one of squamous epithelioma. A radical operation was imperative and was done at once. This was peculiarly difficult, in that both ureters were imbedded in inflammatory exudate. At the time of the removal of the uterus, by cutting away the vagina below the occluding clamps, it was found that all of the involved parts of the vagina on the right side had not been removed. This was removed at once. The pathologist's report stated that the right lateral portion was involved up to the line of the cervix; this was recognized at the time of removal. The examination of the portion removed from the right side showed that no involved tissue had been left behind. The recovery of the patient was uneventful except for prolonged inability to empty the bladder, a condition not uncommon after this operation.

DR. FRANKLIN A. DORMAN asked if they were more uncertain of their diagnosis in frozen slides than if the sections had gone through a special process.

DR. BROUN replied that the sections were compared with other specimens that had ben gone over and in which evidences of malignant disease had been found.

Large Bilateral Bartholin Cysts.—DR. S. WIENER reported this case. The patient was an Italian, twenty-eight years of age, married, who was admitted to Mount Sinai Hospital on September 1, 1911. She had had three children, the last seven months previous to her admission. Ten months ago she had noticed a swelling on both sides of the vulva, which continued to increase in size, was painful, and associated with a moderate whitish discharge. Coitus had become very difficult and painful, and finally had to be abandoned. The uterus corresponded in size to the fifth month of pregnancy, and both labia majora were distended by tense, fluctuating, cystic masses the size of oranges. There was no redness, tenderness, or discoloration of the overlying skin. The left mass was slightly larger than the right. There was no impulse on coughing and no mass or pedicle could be felt in either inguinal region. These masses occupied the entire terrain of the labia majora, being covered on their outer aspect with skin and on the inner side by the labia minora and vulvar mucosa. Exploratory aspiration of the left mass revealed a thick, grumous, chocolate-colored fluid. No gonococci were found in urethral or vaginal smears. At operation both cysts readily peeled out of their surroundings through incisions along the muco-cutaneous junction. The left cyst was removed *in toto;* the right ruptured on removal with partial extravasation of its contents. Both cysts extended up to the pubic rami, which was exposed in the upper angles of the wounds. After complete healing there remained a gaping vulvar orifice with marked cystorectocele in full view. The case presented a number of interesting features. The cysts were bilateral; they were probably the largest on record; there was marked distortion and stenosis of the introitus. The cysts grew rapidly during pregnancy. This last feature could be explained by hemorrhage into the cyst during pregnancy and the trauma on attempts at coitus. There was no ques-

tion but that the proper treatment of large cysts discovered during pregnancy was their total extirpation.

Dr. S. Marx said he had called the attention of the section to his experience with unilateral cysts some years ago. He made his incision at the musculo-cutaneous junction, and there was considerable dyspareunia afterwards. Since then he had made the incision as far away from this point as possible.

A Unique Labor Case.—Dr. S. Marx cited this case in which the baby was born simultaneously through the vagina and through the rectum. He was called in consultation to see a woman, thirty years of age, who had been in labor eight or ten hours. The os admitted two fingers and the head was in the first position. He told the physician to wait and see if it was necessary to send for him again. This was at 8 P.M., and at 2 P.M. the woman's pulse was 110 and the os was fully dilated. Axis traction was made and he thought he could easily deliver the child. The head was in the pelvic basin, and upon making traction he noticed the anus increased in size, soon attaining the diameter of four inches. He then found that the arm, hand, and shoulder were slipping through the anus, while the head was engaging at the vulva. He cut through the tissues separating the vagina from the anus and delivered the child naturally and readily. He found a tear in the rectum about three and one-half inches long. He sewed up the tear and there was good union after ten or twelve days. He did not know how the tear was caused, unless by pressure, as the forceps did not do it, the traction being downwards.

Dr. A. J. Ronga said that Dr. Marx's case was very interesting, there being but few such cases reported in the literature. They had had a case in which the woman delivered herself spontaneously through the rectum. These cases illustrated Klein's conception of the principles governing the pelvic outlet and also perineal lacerations. Klein divided the outlet by drawing a transverse line between the tuber ischii, dividing the pelvic outlet into the anterior and posterior segments. The posterior was the larger of the two. Where the pelvic arch was narrow and flat, and left no room for the head to engage itself in the anterior segment, it naturally had to be born at the expense of the posterior segment. When this deformity of the pubic arch was extreme, the greatest part of the head engaging itself beyond the transverse line, rupture of the perineum was likely to take place at its weakest portion, and with it the rectum was torn, and the head was born through this artificial opening. On the other hand, if the anterior segment was roomy and the pubic arch well-formed, the greater part of the head would be born at the expense of the anterior segment, and therefore the perineum was not likely to be lacerated.

Pubiotomy.—Dr. Sidney D. Jacobson read this paper, giving a report of ten cases and a review of the history of this operation in America. Pubiotomy differed from symphyseotomy, in that in the latter the ligaments which held the pubic bones together were cut with a knife. The operation of pubiotomy was first proposed by Gigli in 1894, and its first successful performance was accredited to Bonardi of Lugano in 1897. The first operation of its kind performed in the United States was done by Dr. Montgomery in Quincy, Ill., the occasion being a persistent face presentation with the chin posteriorly. A search of the literature showed the total number of cases operated on in this country was 53, operated upon by 20 different operators in six different States. Of these 30 were primary or elective, and 14 secondary, that was, they were cases in which attempts at delivery by forceps or otherwise had been attempted previous to the operation. In some of these the life of the child had been seriously jeopardized by previous treatment, and some of the mothers were septic. Of the 30 primary operations, all of the mothers, or 100 per cent., remained alive, while 30 babies, or over 90 per cent., remained alive for over one week. Of the 14 secondary pubiotomies, 11 mothers, or 78.5 per cent., were saved, while 6 babies, or about 42 3/4 per cent., were delivered alive and remained so for a week or more. These figures were an eloquent plea for the performance of pubiotomy in cases of moderately contracted pelves; without it, or with any other known form of treatment, practically all of the children in the secondary cases and a large number of the mothers would have been lost. Most of these cases were operated upon by the subcutaneous method, known as the Döderlein method; only 12 of the cases had been operated on by the open method, and of these the writer had done nine. After describing the subcutaneous method of performing pubiotomy which was in general use, Dr. Jacobson said that early in his experience with this method he had been impressed with two serious drawbacks in this method of operating. One was that after the bone section merely a thin bridge of skin and fat lay between the operator and the divided tissues. This bridge was of no value to the patient, and was harmful because it prevented the surgeon from using proper surgical methods to stop hemorrhage, which was sometimes serious. The second drawback was that under this bridge of skin a hematoma often formed, which might become infected and cause tedious suppuration and sepsis. The writer, therefore, used the open method of operating by dissecting down to the bone before dividing it. Thus all hemorrhage could be easily controlled. He also placed the patient on her back, with her legs extended, during operation. Thus the intraabdominal pressure was not raised, and consequently the baby's head was not forcibly jammed down into her pelvis the moment the bone section was completed, and the ends of the divided bone were not violently pried apart; thus extensive vaginal lacerations were avoided. The technique employed by the writer was simple and within the compass of any man claiming recognition as an obstetric surgeon. The patient's pubic region was submitted to a dry shave and her vulva and adjacent parts painted twice with tincture of iodine. If there was a purulent vaginal discharge the interior of the vagina was also painted with iodine. The patient being placed on her back and anesthetized, the operator found the left pubic spine by palpation and made an incision about four inches long just median to the spine and almost parallel with the left labium majus. The incision was longer if the patient was fat. This incision was deepened until the whole pubic bone came into view. Meanwhile a few small bloodvessels would have to be clamped. The saw-carrier or pubiotomy needle was passed around the back of the bone, keeping close to its posterior surface, from above downwards, until the lower edge of the pubic bone was reached. The carrier was passed just median to the pubic spine. When the point of the carrier had emerged into the wound under the lower edge of the bone, the saw was attached by a stout thread, and the carrier, being withdrawn, drew the saw up behind the bone with it. The carrier was detached from the saw and the handles were attached, and then the bone was sawn through by the aid of sight. As the bone section was completed the saw was discarded and a sterile gauze packing was pushed behind the cut ends of the bone, between its surfaces and in front of it, until the wound was full. The lips of the wound were brought together with 4 to 6 silkworm or Pagenstecher sutures and tied in bow-knots. The patient was slowly brought into the lithotomy position, care being taken that the toes were not everted, as this separated the bone ends and tore the soft parts. Forceps were then applied and the baby was delivered. After delivering the placenta, the vagina was packed with sterile gauze to prevent the possibility of postpartum hemorrhage. A little roll of sterile gauze was

placed over the line of incision and a three-inch-wide strip of adhesive plaster placed over that to keep out discharges. The urine was drawn by catheter, and, if free from blood, no injury had been done the bladder. About twelve hours later the dressing was removed. The bow-knots of the sutures were untied but left in place to close the wound after the packing had been removed. Gauze and plaster dressing was then applied after leaving a small gauze drain in the lower angle of the incision. This drain and dressing were changed daily and the stitches removed on the fifth day. The patient was catheterized every five hours for the first week. Otherwise the after treatment was the same as after instrumental delivery. After giving a brief history of the ten cases upon which he had operated, Dr. Jacobson summed up the advantages of pubiotomy as follows: 1. Where the disproportion was slight the patient might receive the benefit of the test of labor. This would protect the woman from unnecessary surgical interference. 2. The part at fault was operated upon and the pelvis was permanently enlarged. 3. The patient was not subjected to a dangerous or mutilating operation. 4. The child was not injured in the delivery. 5. The operation did not leave any permanent disability. 6. The patient might be safely delivered, even if exhausted or infected. 7. Prolonged anesthesia not being necessary, delivery might be performed in the presence of organic heart disease, and rapidly completed. 8. Statistics showed better results by this method than by any other in moderately contracted pelves.

Dr. S. Marx said that he was not only opposed to this operation, but to symphyseotomy as well. He felt that he could almost guarantee that an expert could do one hundred cesarean sections without mortality and the women would be left in good condition. They would not get 100 per-cent. recoveries in pubiotomy and the women would not be left in good condition. He had seen women injured for life as the result of pubiotomy. He had recently seen abroad three women who had been reported as cured; one had a hole in her bladder, a second had not walked for six or seven weeks, and the third had a permanent urethral fistula. He had never seen such wonderful results as Dr. Jacobson had seen. He had seen rise of temperature, necrosis of the bone, sepsis, hematoma, and other conditions of serious import develop. Dr. Marx compared these results to those that followed a good, clean, elective or non-elective cesarean section. Of his own 25 cesarean sections all had recovered except one, who was operated on during an acute pneumonia. Dr. Marx said that Dr. Jacobson's description was not full enough; he spoke of women with contracted pelves, of women with small pelves, but nothing was said about the position or the adaptability. He cared not what the pelvis measured, but he did care about the irregularities. If they could get the head to engage it would go through. In the case of symphyseotomy that Dr. Jacobson reported as having been done in Illinois, why did not the physician try to correct the position? In those cases in which a suspicion arose that a pubiotomy might be required, he advised the Walcher position; with the head in the pelvis he applied the forceps. When the waters had escaped it might be well to attempt an elective high forceps in the Walcher position. In those cases in which the child was dying or dead, there was a useful field for perforation, and he used the perforator to-day more than ever before. The best results, however, were obtained by doing a clean cesarean section. He did not care so much about the mortality rate as about the morbidity rate.

Dr. John O. Polak said the time had come when the delivery of the full-term child must be made by forceps, pubiotomy, or cesarean section. The forceps should be used only in those patients who had had the test of labor and where the head could be engaged in the pelvis. Version had no place in contracted pelves, particularly the kind one met with around New York. The great trouble with pubiotomy was the injury inflicted on the soft parts. It was well enough to say "open the pelvis by a pubiotomy incision and the head will fall in," but the operation was not completed by the descending head. The operation of pubiotomy did not finish the delivery. Often after the operation the woman was subjected to the same injuries that were attendant upon a difficult forceps operation, and these injuries were serious so far as the woman's future comfort was concerned. He thought that perhaps he was too enthusiastic in regard to elective cesarean section since Dr. Humpstone and he had operated upon 60 cases without a death, and they found that the length of time that the women had been in labor made no difference in the mortality. He thought their success was due to rapid and clean technique. Last year Dr. Polak had had occasion to perform a cesarean section on a woman who had previously had a pubiotomy performed. He did the cesarean section because of an exostosis at the line of the pubiotomy wound. This showed that pubiotomy did not always enlarge the pelvis. He was opposed to craniotomy and did fewer and fewer, because he believed the child had certain rights.

Dr. A. J. Rongy thought that pubiotomy had a definite field in modern obstetrics; an operation that had been performed over 500 times by our best obstetricians ought not to be condemned, particularly by those who had had no experience with it. Pubiotomy should never compete with cesarean section. Cases in which cesarean section was indicated, pubiotomy was contraindicated, and *vice versa*. Craniotomy must be eliminated from the category of modern obstetrics if the child was fully viable. Personally, Dr. Rongy said he would withdraw from a case if asked to perform a craniotomy on a living child. The method that Dr. Rongy followed was that of Doderlein, or the partially closed method, as he thought the open method exposed too many areas for infection and exposed the bony surfaces unnecessarily. The bleeding could usually be closed by compresses and packing the vagina, and the post-operative dressings and treatment were very simple. He allowed the patient to move about in bed at the end of the third day and allowed her to get up on the fifteenth day if her physical condition permitted. He found that in his cases bony union did not take place, and the reports from various clinics showed that fibrous union took place in two-thirds of the cases. There was no permanent enlargement of the pelvis, as claimed by pubiotomists. Among a series of 50 cases in Shauta's clinic, 44 had subsequent deliveries and only three of them delivered spontaneously. Pubiotomy should be performed only in misjudged or neglected cases.

Dr. E. K. Brown said that the operation of pubiotomy was not an operation of election because of its sequelæ. In Dr. Jacobson's cases they should have the full details of the measurements of the pelves of women operated on by him and also the measurements of the fetal heads.

Dr. Ralph Tousey said that, as he recollected in studying William's obstetrics, the operator was advised to raise the periosteum from the pubes and to saw underneath it. He asked if that was a necessary part of the procedure.

Dr. Rosalie Slaughter Morton asked Dr. Jacobson about the weight of the children born spontaneously in two of the pubiotomies that he reported. Was the second child less in weight than the first? Also was there a solid bony union following the operation in these cases?

Dr. S. Wiener said that five years ago, when he was in Berlin, he saw many of the bad results following pubiotomy. On one case in particular there was a tremendous injury to the bladder, for which the assistant was blamed because he did not push hard enough against the femur. It required three subsequent operations to heal the result-

ing vesicovaginal fistula. In Germany they were forsaking pubiotomy and going back to cesarean section.

Dr. Clinton Beecham Knapp said he had had but one case in which he had resorted to pubiotomy. Previous handling had excluded cesarean section, and hebotomy was done and the child came through easily with the use of the forceps, but died a day or two later of cerebral hemorrhage. He advised Dr. Jacobson not to consign his high forceps to the scrap heap, as he might need the forceps to bring the head through after he had performed pubiotomy. He did not think that the author of the paper had sufficiently considered the danger of rupturing the bladder. The indication for pubiotomy was where the mother was not strong enough, or where previous handling so increased the danger of infection that cesarean section could not be risked. In version or breech cases, where there was much doubt as to the delivery of the after-coming head, he felt that it was a safe procedure to place the Gigli saw.

Dr. Jacobson, in closing the discussion, said that he respected the opinion of Dr. Marx as coming from an obstetrician of large experience, but he differed from him in a few minor points. Dr. Marx quoted a series of 50 cesarean sections done by someone else without any mortality; these were probably picked cases which had not been subjected to long labors and various other attempts at delivery. Under similar circumstances he had quoted a series of 30 pubiotomies without maternal mortality. The most brilliant results shown by pubiotomy were in cases that had been in labor for a long time and had been handled so much that the advocate of cesarean section would not dare to operate. One of the most skillful of New York obstetricians had shown a mortality of 14 per cent in a long series of cesarean sections done in unpicked cases, and he had at his command trained assistants and a first-class hospital organization. Dr. Jacobson said he had never seen one case of hopeless crippling of the patient, either in his own practice or that of any other operator. That occasional cases might suffer from injury to the soft parts, due to pressure or to gouging with the forceps, was not denied, but that they should be charged to the safe operation of pubiotomy was not quite fair. Dr. Marx said he preferred version in cases of contraction of the pelvis. It was precisely in this class of cases that the head could not be delivered in time to save the child. The fetal mortality here was absolutely prohibitive. Personally, he felt that craniotomy on the living child was absolutely unjustifiable. Only 0.5 cm. increase in the conjugate diameter of the pelvis could be gained by the Walcher position, and usually only a few millimeters were gained in this way. The morbidity after the operation of pubiotomy had been highly exaggerated by the opponents of this operation. The liability of breaking the saw was referred to, and this was of frequent occurrence unless certain precautions in the technique were observed. The saw must not be bent at an acute angle and the sawing must be done very deliberately and the whole length of the saw used. The sawing must be done very slowly or the friction raised the temperature so high as to break the saw. He could not agree that the passage of the child after pubiotomy tore the vagina. Two factors operated after the division of the bone; firstly, the patient's legs, being bent over the abdomen, raised the abdominal pressure and forced the fetal head against the pubic bone; this gave no time for the soft parts to accommodate themselves. Again, by allowing the toes to become everted too much the head of the femur, acting through the acetabulum, acted as a lever to pry the end of the cut bone apart, and proportionately to the eversion of the patient's feet would her soft parts be torn. Only after all was ready for delivery were the legs slowly and evenly raised and made fast in the lithotomy position; but the thighs were kept at a right angle to the trunk, so as not to raise the intraabdominal pressure until the child had been delivered. The feet were not allowed to be everted any more than was necessary to gain sufficient bone separation for easy delivery of the child. In reply to Dr. Tousey's question, it might be said that it was not proper to raise the periosteum from the bone before section; such a procedure might induce necrosis of the bone. As to Dr. Morton's question regarding the size of the children subsequently delivered after pubiotomy, his impression was that they were average children, whose heads were a little larger and harder than those gotten at the time of the pubiotomies. The pelvic bone did not, as a rule, unite solidly, but the patients walked perfectly well after the parts were healed.

Election of Officers.—*Chairman*, Dr. Franklin A. Dorman; *Secretary*, Dr. George W. Kosmack.

THE WESTERN SURGICAL ASSOCIATION.

Twenty-first Annual Meeting, Held at Kansas City, Missouri, December 18 and 19, 1911.

The President, Dr. Amos W. Abbott, Minneapolis, Minnesota, in the Chair.

(*Concluded from page 190.*)

Treatment of Cancer of the Uterus by the Actual Cautery, with a Practical Method for Its Application.—Dr. James F. Percy of Galesburg, Ill., stated that he had improved his technique in using the actual cautery in otherwise inoperable cases of cancer of the cervix and body of the uterus, as follows: "(1) The abdomen is prepared as for any abdominal operation. (2) The patient is put in the full Trendelenburg position. (3) An abdominal incision is made just sufficient to admit one or two fingers of an assistant into the pelvis. In a thin patient one finger is enough. (4) A fever thermometer indexed to register at least 250° Fahr. is introduced through the urethra into the bladder after the urine is removed by catheter. A second similar thermometer should be in readiness for use in the rectum, if it is necessary to cauterize deeply posteriorly. The fingers can be used here also, and may be all that is necessary. (5) The cautery is applied in the vagina through a speculum after the pattern of that of Ferguson. This speculum is made on the plan of a thermos bottle. (6) There is no use of attempting this work unless the cautery used is perfect in its action, namely, has more heat under control and at command than will ever be required." The author referred to the use of the cautery in this disease twenty years ago by Dr. John Byrne of Brooklyn, N. Y., and commended it. The author based his technique on the statement of Loeb, that a section of mouse cancer, when frozen, would grow again when transplanted; but if the temperature of a control section was raised to 113° Fahr. or more it could not be successfully grown. A special form of heavy cautery was used which would raise the temperature in the pelvis to 120° Fahr. The author showed that by the technique described, the use of the cautery could be made just as accurate and finished as when the knife was used. If all cases of cancer in the region of the body under consideration were submitted to the improved cautery operation described, the author was more than convinced that practitioners would obtain not only the advantage of no primary mortality, but in addition a largely increased percentage of lives greatly prolonged in comfort, with freedom from hemorrhage, exhausting an offensive discharge, and mental distress.

Tubal Sterilization.—Dr. Lawrence W. Littig of Davenport, Ia., read a paper on this subject in which the following conclusions were drawn: (1) That animal experiments, the ligation or excision of pathological tubes, and the results of like operations on normal tubes proved

conclusively that tubal ligation, with or without excision, was not an efficient measure to prevent conception. (2) The only operation which gave a promise of success was excision of all or a part of the tube with a deep wedge-shaped incision of the uterine cornu, including the *pars uterina* of the tube, the uterine defect to be closed with a musculo-muscular, and a sero-serous row of sutures. (3) The anterior abdominal approach was the easiest, the simplest, and the safest. (4) Granting that the state had the right to sterilize its mental and moral delinquents, tubal ligation, as legalized in Iowa, considering its remote possibility of success, and its ever-present, although vanishing danger, was an unjustifiable operation, entirely without promise as a means to lessen the procreation of the unbalanced. (5) In medical practice tubal sterilization was but rarely justifiable because it did violence to the most deeply rooted of all instincts, after that of self-preservation. (6) Considering the almost fiendish pertinacity with which the female economy conserved the function of the Fallopian tubes, the efficiency of vasotomy or vasectomy might also be questioned unless Kipling were right when he said, "But the woman that God gave him, every fiber of her frame, proves her launched for one sole issue, armed and engined for the same, and to serve that single issue, lest the generations fail, the female of the species must be deadlier than the male."

Artificial Tendons and Ligaments of Silk in the Surgical Treatment of the Paralyses.—Dr. NATHANIEL ALLISON of St. Louis stated that his experience covered a considerable number of cases and dated back to one year and a half ago, when the operation of anterior foot suspension was first performed. Since then twenty odd cases had had the method employed to afford stability at their ankles in one form or another. But one case had been operated upon to check hyperextension at the knee. In none of these cases had the silk shown any tendency to come out, nor had there been an infection. The after-treatment of these cases should be carefully overseen for at least a year. Plaster-of-Paris dressing must be worn for the first six weeks. After this braces might be supplied, which would support the limb and protect the artificial tendons from undue stress, the idea here being to give the tissues a sufficient period of time to produce fibrous tissues in sufficient quantity to insure permanency of the support.

A New Apparatus for the Reduction of Fractures of the Lower Extremity.—Dr. CHARLES H. LEMON of Milwaukee said that this instrument was one of precision and when used intelligently much could be accomplished with it. That it would enable surgeons to obtain better results than were possible by Buck's extension was his experience after five years of personal use. It had made unnecessary the general operation of closed as well as of many compound factures by enabling the surgeon at his leisure and without the aid of assistants to completely extend fractures. By its use it was his hope that more definite apposition of fragments in all parts of the leg would be made possible because the rods which carried the footpiece from which the extension was made could be placed in any position the human leg could be. It had overcome the difficulty recognized by Sir Ashley Cooper and the limitation of Mr. Lane's plate in intracapsular fractures of the femoral neck. That this instrument might prove in the hands of others the valuable adjunct it had proven to himself in the treatment of fractures of the lower extremity was his reason for exhibiting it at this meeting.

Chronic Brain Abscess of Traumatic Origin.—Dr. WILLIAM JEPSON of Sioux City, Ia., reported the results in six cases of chronic brain abscess of traumatic origin which had been submitted to operation. There was one recovery among the three cases from gunshot wounds and two recoveries among the other three cases from fractures produced by means other than missiles. Dr. Jepson pointed out that in all cranial fractures assuming the type of punctured wounds there existed a great tendency to the production of a chronic abscess, which he designated as an encapsulated infection, and as long as the capsule held, which might be many years, the same would be without symptoms, as the capsule separated the tissues to a far greater extent than that of destroying them. Such capsule, however, sooner or later gave way, converting a latent into a potential infection, and the development of symptoms indicative of acute inflammation followed. He spoke of the danger of infecting the arachnoid space, a danger which should be guarded against by a not too rapid escape of the pus.

The Choice of Technique in Enterostomy Incident to Operations for Intestinal Obstruction.—Dr. JOHN P. LORD of Omaha favored refinement in the technique of enterostomy to render its application less objectionable than it was when the operation was performed by the present well-known methods, which he considered too crude. Their very objectionableness prevented their use except as a last resort. The frequent early use of an unobjectionable method improved results. The drainage of the bowel in chronic obstruction as well as in acute made for safer surgery. Venting by an enterostomy tube in uncertain or insecure sutures, especially in complicated cases in resections of the large intestine, removed the element of gas distention and allowed rest to the bowel, a necessary condition to insure primary union. The technique favored was practically identical with an E. J. Senn gastrostomy. Leakage had never been troublesome, and in all cases that survived closure was complete in a short time. The literature showed the use of the pursestring suture of the intestine about a catheter, but little was said about multiple pursestring sutures as in a Senn gastrostomy. Dr. Lord contended that the simplicity and safety of the method favored made the indications for enterostomy more frequent, and if it were often used and had a more general early application it would make for safer and more satisfactory intestinal surgery incident to operations for obstructions.

The President's Address: "The Western Surgical Association."—Dr. AMOS W. ABBOTT of Minneapolis said he believed the secret of the success of this association was this: the criticism in this association was not only honest but capable. Here the work, not the individual, was discussed. The members felt that the criticism was just and that it came from an authority, equal and often higher than his own. They came for the truth, and when they were through they felt that they had it, and that, small as the footing might be, each member knew where he stood. No member of the association would willingly fatten on an error that would do injury to his clientèle. He wanted to get at the absolute scientific value of his work. He had no vanity to sacrifice, but wanted only to take back to his people facts on which he could depend. On the other hand, when the approval of members had endorsed his work he was assured of its reliability and was proportionately comforted and encouraged. These, he believed, were the chief reasons for the success of this association

Infection of the Retroperitoneal Lymphatics.—Dr. JAMES E. MOORE of Minneapolis said that they were all familiar with perinephritic abscesses and retrocecal abscesses when the appendix was outside of the peritoneal cavity, but, aside from these, comparatively few cases had been reported in which the abscess was known to be of retroperitoneal origin. We would naturally expect this large space behind the peritoneum with its abundant areolar tissue and free lymphatic communication with parts so frequently the seat of infections to be a very common location for abscesses. The chances were that owing to

the inaccessibility of these parts infections, and even abscesses, often occurred here that were not recognized. When there was an infection here the intestines usually became distended, which added to the natural difficulties of examination; when chills, fever, and sweating were present, the cause of which was not found in any of the usual locations, or when the symptoms continued after thorough drainage of pelvic or abdominal abscesses the retroperitoneal space should be suspected. It was quite possible that in many instances where patients had died from sepsis without the abscess having been discovered it was located in this region. The presence of tuberculous abscesses in this location had been very frequently recognized. The reported causes of nontuberculous abscesses in the retroperitoneal space were typhoid fever, appendicitis, salpingitis, infection following abortion and parturition, and suppuration of the inguinal glands. In some cases following parturition infection had manifested itself as late as three months after labor. A few cases had been reported without apparent cause. The writer's experience was limited to four cases, the first two occurring years ago before laboratory facilities were at hand.

Failure of the Colon to Rotate.—Dr. Charles H. Mayo of Rochester, Minn., said that the relative rarity of these obscure intraabdominal abnormalities and the fact that they so infrequently gave rise to definite symptoms explained in part why a diagnosis was so seldom made. The common afflictions, such as harelip, club-foot, imperforate anus, anomalies of external genitalia, etc., usually came under the surgeon's care in infancy or early childhood. But within the abdomen congenital deformities were so efficiently concealed that only a small percentage of them was found until adult life was reached, and then only at operation or autopsy. The various phases resulting from nonobliteration of the vitelline duct, dermoid cysts, anomalies of the female genitalia, and variations in the position and relationship of the large intestine were familiar examples of these conditions. Because of congenital or acquired openings in the diaphragm, much of the colon with other abdominal viscera might be located in the pleural cavity. A partial rotation might leave the cecum at any point between the normal and the right under-liver position, or the left umbilical or left pelvic position. In the event of such abnormality there might be failure to find the appendix at operation and the congenital position should be considered probable when no colon was found on the right side, and positive if the duodenum was found uncovered by colon and with a mesentery. Failure of the colon to rotate should be considered as a possible cause in cases of obscure inflammatory conditions in the left or middle pelvis, or in the left iliac fossa. Approximately three hundred cases of complete transposition of the abdominal viscera had been reported in the literature. In six cases observed at St. Mary's Hospital they operated three times for left-sided appendicitis, twice in acute abscess. Very little was found in the literature as to failure of the colon to rotate, although it was undoubtedly a condition which should be considered as more frequent than complete transposition. The condition might be found described under various anomalies of the duodenum as well as of the colon. They had observed five of these cases during the past two years in operating upon the abdomen, and in only one of the cases was the abnormality diagnosed before operation. Dr. Mayo reported five cases observed at St. Mary's Hospital during the past two years.

Nitrous Oxide Gas and Oxygen Anesthesia.—Dr. Clifford C. Collins of Peoria, Ill., read a paper on this subject. The advantages of nitrous oxide gas and oxygen, as pointed out by him, were: (1) So far no one had been able to discover that it had any harmful action on any tissues of the body when administered in anesthetic quantities. (2) It had no odor, and the patient was not aware, so far as any odor was concerned, that he was taking an anesthetic. (3) It produced no shock of itself, and the total amount of shock from an operation was much less under gas and oxygen than under ether. (4) It did not have any harmful action on the leucocytes, therefore its use was indicated in infections. (5) Its danger was not increased by frequent subsequent administrations. (6) There was much less postoperative vomiting than from ether or chloroform. The disadvantages were: (1) It was considerably more expensive than ether or chloroform. (2) It did not produce deep relaxation of the muscles. (3) The anesthesia was lighter and more transient. (4) It required a more expensive administration apparatus. The disadvantages of gas and oxygen concerned the surgeon and anesthetist, but did not add any discomfort or danger to the patient. With an apparatus like the Teter nitrous oxide gas, oxygen, or ether might be administered separately or in any desired combination. In this way the anesthetics might be fitted to the patients and not the patients to one anesthetic.

Tuberculosis, Solitary and Apparently Primary, of the Fallopian Tubes.—Dr. Albertus J. Burge of Iowa City, Ia., reported two cases of tuberculosis of the Fallopian tubes. The sections in each case showed well marked tuberculosis in the partially destroyed or degenerated mucous and muscular walls with distinct giant cell formation. He predicted that the future would recognize distinctly the tendency of the female adnexa to develop primary tuberculosis as did the epididymis of the male. If so, what should be the treatment accorded such? Would it be the same vigorous, radical, and summary course which the analogous disease in the male merited and now received? In view of the added dangers of an intraperitoneal location in the female, he ventured to say that it would, saving the ovaries when free and safe, but in nowise temporizing with the tuberculous infected tubes.

Dr. John B. Murphy of Chicago stated that Dr. Burge's paper had interested him from several standpoints. First, from the pathological findings; second, from the clinical history; third, from the association of this lesion with hemorrhages from the uterus, and, fourth, from its surgical treatment. The reason for the deposit of tubercle bacilli in a tube was not definitely settled. Whether it was of hematogenous origin in the tube, or of hematogenous origin in the vas deferens, or the epididymis, which was a common point of location in the male organs of generation, was a question. It was his belief that infection in the tube was more commonly through the peritoneum or through the uterus, and that tuberculosis of the uterus was a more frequent lesion than was generally believed. Both of Dr. Burge's cases showed evidences of mixed infection, and not a pure infection. When there was a pure infection of the tube the fimbriated end was open. It was the only type of infection of the tube that retained the patency of the tube during the inflammatory process. In the other types of infection of the tube the tendency was at once to the closure of the tube by agglutination to the neighboring structures. Where a tube remained open the clinical course was almost identical with that of recurrent appendicitis. The patient would have a period of relief—in fact, of good health—followed by a sudden attack of pain, nausea, and vomiting, local sensitiveness, elevation of temperature, and often a discernible effusion in the peritoneal cavity. Examination through the vagina or through the rectum usually showed a thickening of Douglas' pouch in the class of cases of the type he mentioned. In the type of case Dr. Burge had reported here once the tube became closed it did not give the recurrent appendicitis syndrome of symptoms as did the open fimbriated end. Perforation of the tube on the side of tuberculosis, as mentioned in the paper, was not uncom-

mon. When it did occur it caused a limited peritonitis, which usually rapidly circumscribed itself and underwent repair. The peritoneum had such greater resistance against tuberculosis than any other tissue in the body that it rapidly healed up. In the treatment of these cases removal of the tube with the encapsulation of the ends sufficed for the cure of the local condition, and not only that, but the extensive peritonitis that might have resulted from repeated attacks of leakage from the end of the tube entirely repaired itself.

Observations on the Present Status of Surgery for Cancer of the Breast.—Dr. E. S. Judd of Rochester, Minn., said that tumors of the breast might be divided into two groups, benign and malignant. So far as was known at the present time, a differentiation other than microscopic could not be made between a benign tumor and a very early malignant one. They should all come under the same line of treatment, namely, radical excision of the malignant tumors and removal of the tumor followed by radical excision if the growth proved malignant in the supposedly benign type. Age was no longer considered an important factor in determining malignancy. Handley believed that cancer originating in the breast disseminated through the lymphatics in the fascia, and that the embolic theory had been accepted chiefly because there was no proof against it. While it was true that the muscles were seldom involved as compared to the fascia, at the same time he had recently observed several cases in which the lymphatics penetrating deep into the muscle were extensively involved. The frequency with which mammary carcinoma produced metastases in the bones was well known. The sternum and ribs were the most frequently involved, and this occurred by direct extension. The femur, bones of the spine, and humerus came next in the order of frequency. It was often advisable in cases of cancer of the breast to have *x*-ray plates made of the bones most frequently invaded, since it was obviously useless to remove the breast should one of these bones be involved. Two hundred and sixty-four cases of carcinoma of the breast had been observed in the clinics at St. Mary's Hospital within the past two years. Of this number two hundred were considered operable and sixty-four inoperable. In order to make an early positive diagnosis it was necessary to remove for macroscopic and microscopic examination all supposedly benign and doubtful neoplasms. The technique of radical amputation of the breast had changed but little in the past few years. A large amount of skin, equidistant in all directions, should be removed. The most important part of the technique was the removal of a very extensive part of the superficial and deep fascias. This dissection should begin above the axillary structures, include the pectoral muscles and fascia of the axilla, and extend down over the rectus muscle, taking in a part of its fascia. In removing the pectoralis major the fascial incision was carried to the sternum and from there outward to the large muscles of the back. If there were many skin nodules, or if the integument was brawny and edematous, although the local lesion could be entirely removed, in all probability there were internal metastases or bone lesions and the condition was hopeless. The prognosis as to the probability of a cure in a case of carcinoma of the breast would depend (1) on the length of time the neoplasm had been developing; (2) on the degree of outlying involvement; (3) the activity of the gland, which would be determined by the age of the patient and the relation to a period of lactation, and (4) the thoroughness of the removal of the gland-bearing fascia.

Sarcoma of the Testicle.—Dr. Arthur C. Stokes of Omaha reported a case of sarcoma of the testicle, after which he drew the following conclusions: (1) Typical sarcoma of the testicle occurs more rarely than atypical. (2) Tumors of the sarcoma type, but atypical, occur more frequently than those of the carcinoma type, Ewing to the contrary notwithstanding. (3) Typical sarcoma of the testicle occurs occasionally, but always arises in the epididymis or tubules, and never in the rete testis. All tumors taking on a carcinomatous appearance are teratomas in origin with the epiblasts predominating. (4) The mixed tumors of the testicle originate in the rete testis in tissues which, according to Grawitz, have their beginnings in primitive kidney embryonal tissue or mesoblastic origin carried down in the descent of the testicle. According to Waldeyer, they originate in the sexual cell, which has been subjected to some form of irritation. This last theory agrees more clearly with the clinical picture than does the theory of Grawitz. (5) The literature on prognosis is so fragmentary and imperfect that one has been unable to lay down any principles for operation from the accumulated records, but judging from the pathology of the tumor by the time a clinical diagnosis is possible an operation as radical as Bland Sutton's should be done, and the removal of the testicle and cord only begs the question and is never indicated.

Strangulation of Intestine Beneath a Persistent Inguino-Genital Ligament.—Dr. C. H. Wallace of St. Joseph, Mo., reported a case illustrating a very rare condition. The case presented the unusual features of cryptorchidism with a well organized embryonic inguino-genital ligament underneath which a loop of small gut became strangulated while the patient was in the act of lifting his leg. The development of a free band extending from the retained testes to the internal abdominal ring brought forth some controversy inasmuch as the settlement of considerable accident insurance was involved in the case. On the one hand, it was held that the inguino-genital ligament, which later became the gubernaculum, existed as a retroperitoneal structure similar in peritoneal relations to the ureter, hence the impossibility of the intestine being caught beneath it. This view appeared to be reasonable until further study was made of the development and descent of the testes. In order to clear up the question satisfactorily, a personal letter was addressed to Dr. George S. Huntington, Professor of Anatomy in Columbia University, New York, explaining the findings at operation. His letter of reply was freely and literally quoted in what followed: According to Professor Huntington, "there was unquestionably in this case the exceptional condition of cryptorchidism in which the testis remains, after reduction of the Wolffian body proper, in relation to the caudal pole of the permanent kidney, instead of descending, as it usually does, to the inguinal ring or some point within the inguinal canal." The constricting band was undoubtedly the inguino-genital ligament of the embryonic testis which normally becomes the gubernaculum. That it existed as a free band capable of strangulating the bowel is not remarkable. "All abnormally persistent embryonic structures, which raise the colon lining into folds, tend, if they persist in the adult, to become free structures traversing the peritoneal cavity. This is accomplished by absorption of the thin-layered sheet of colon lining which forms the foundation of the original fold of embryonic peritoneum developed by the growth of the related structure." An example might be found occasionally in the persistence of a free band extending from some point along the terminal portion of the ileum to the umbilicus. This was a fibrous cord representing persistent omphalomesenteric artery. Very rare was the condition of a persistent band representing the inguino-genital ligament. If persistent, however, the same law of absorption of mesentery had been followed. Originally the mesenteric folds performed a blood carrying function. "In the case of a descendant and rudimentary structure, persistent in the adult, this primitive mesenteric fold lost

its original significance as a blood carrying membrane The structure to which it originally brought vessels degenerated into a fibrous cord, with very slight vascular relations and the mesenteric peritoneal fold by means of which it was originally suspended within the peritoneal cavity, began to be absorbed in certain regions, producing lacunæ or perforations. The confluence of these areas of absorption tended to the formation of larger fenestra between the parietal peritoneum and the band, and finally by a continuation of this process the band, whatever its original significance and purpose might have been, traversed the abdominal cavity of the adult in the direction of its original embryonic relation and might act as a constricting or strangulating agent if intestinal coils were caught beneath it, or between it and the abdominal walls Another rather interesting feature in the history of the case was the apparent relaxation of the band while the patient was in the act of lifting the leg, thus permitting a long loop of intestine to slip beneath it.

Congenital Malformations of the Ureters.—Dr Daniel N. Eisendrath of Chicago read a paper on this subject in which he drew the following conclusions: "(1) Congenital malformations of the ureters were formerly thought to be only of interest to the pathologist. (2) The surgical importance of these malformations is just beginning to be appreciated. (3) Four of his cases were found to give rise to clinical symptoms sufficient to require operation. The fifth case was a specimen obtained at autopsy. (4) The clinical picture in these cases varies. In some the abdominal tumor is the most prominent symptom These are the cases which are generally spoken of as congenital hydronephrosis, where the obstruction is close to the renal pelvis. A second clinical variety is that in which the sausage-shaped tumor extends from the costal arch downward. A third variety is where a protrusion of the lower end of the ureter into the bladder exists. A fourth variety is where the clinical picture is that of a renal infection. Some of these cases may be very difficult to diagnose on account of their resemblance to other varieties of intraabdominal infection. The origin of all congenital malformations of the ureter is undoubtedly a persistence of fetal conditions The principal varieties found at operation and autopsy are these: (1) No lumen for the entire length. (2) Narrowing or localized absence of lumen: (*a*) ureteropelvic junction; (*b*) upper third alone; (*c*) both upper and lower thirds (*d*) at vesical and (cystiform protrusion). (3) Spiral twists, usually one or more. (4) In none of the cases was the lesion due to any accessory renal vessels or any extraureteral inflammatory process."

The following papers were also read: "Chronic Infective Synovitis," by Dr. W. W Grant, Denver, Col.; "Complications of Displacements of the Colon," by Dr. Carl E Black, Jacksonville, Ill.; "Surgery of the Thymus Gland, with Demonstration of Intratracheal Insufflation of a Dog," by Dr. B. Merrill Ricketts, Cincinnati, Ohio; "Treatment of Acute Intestinal Obstruction Accompanied by Impairment of Intestinal Vitality," by Dr. Van Buren Knott, Sioux City, Ia.; "Further Observations of the Regeneration of Bone and Reproduction of Joints," by Dr. John B Murphy, Chicago, Ill.; "Some Effects of Anesthesia Upon Toxin Resistance," by Dr. John L. Yates, Milwaukee, Wis.; "The Results in the Treatment of Cancer of the Uterus by the Actual Cautery, with a Practical Method for Its Application," by Dr. James F. Percy, Galesburg, Ill.

Officers.—*President*, Dr I. L. McArthur, Chicago; *First Vice-President*, Dr. Walter B Dorsett, St. Louis, Mo.; *Second Vice-President*, Dr. B. Merrill Rickets, Cincinnati, Ohio: *Secretary-Treasurer*, Dr. Arthur T. Mann, Minneapolis.

Cincinnati, Ohio, was selected as the place for holding the next annual meeting

ON THE PRACTICAL UTILITY OF THE DISTINGUISHED CONSULTANT.

By CECIL KENT AUSTIN, M.D.,

PARIS, FRANCE.

THE American physician to whose lot it falls to pursue his profession in foreign parts, and especially in such an important and favorite center as Paris, finds himself placed in circumstances that differ very materially from those encountered by his confrères at home. The particulars wherein the two careers vary are many, but the only one that need be referred to at present is this: for very natural reasons the practice of the man in Europe is limited almost entirely to his fellow-countrymen; and since either to live or to travel abroad presupposes a certain degree of ease in money-matters, temporary or permanent, it follows that his patients belong almost without exception to the well-to-do element of society, and that he sees nothing whatever of the poorer classes. The outcome of this situation is a twofold one: the poorer patients being often the most interesting and appreciative that one meets, the physician practising abroad is deprived of a very welcome consolation in his weary career; on the other hand, the American clients with ample means, and more especially the very rich, are, I think by universal consent, the least grateful and most trying individuals all around that can fall into a medical man's hands. On this point also there would be a great deal to say, but to-day I must limit myself to the aspect of the question that particularly concerns the present subject, which is that the wealthy patients have been so utterly spoiled by the power that is conferred by the possession of unlimited money, and are in general such confirmed sceptics in everything concerning medicine, that they are seldom satisfied with one professional opinion on anything that may be the matter with them, no matter how trivial the complaint may be, but at once clamor for farther advice. "Now, doctor, you say that this is an inflamed bunion?" "Yes." "Well, who then is the very best specialist in town on that disorder? I should like him to see the case with you and give it his closest attention." This is the cry we unfortunate exiles hear every day, until we get so sick of specialists and consultations that we frankly wish them and the patients comfortably in Hades. But the result of this state of affairs is a curious one: the American general practitioner in Paris thereby acquires a wider knowledge of such matters and becomes a better judge of consultants, their natural history and habits and their intrinsic merits, than any other medical man, I imagine, in the entire universe; and it is on the strength of an experience already long and checkered in this particular that I am making bold to say a few words on this subject to-day.

It will perhaps be well first to make quite clear the meaning of my title. Thus from the start many specialists have naturally to be excluded from the sort of consultants to which I refer, for the evident reason that no practitioner nowadays pretends to have more than a summary knowledge of certain branches of medicine, among which can be mentioned in the first rank mental, nervous, and ocular diseases; there are also medical men who do not care to handle nose, throat, and ear complaints, dermatology, venereal, and genitourinary diseases, or obstetrics, and to the physician of this category the specialist is of course a necessity, though this need not have been the case had his early training been more thorough and complete. Again, no one questions the utility of the consultant to the young practitioner not yet possessed of the age and experience necessary to impose respect for what he says; in such instances the presence of an older man with a well-established reputation will do wonders at a critical juncture by substantiating the junior's diagnosis, approving of the treatment followed, tranquillizing the patient, satisfying the relatives, smoothing down the feathers of the regular attendant, which were beginning to ruffle, and stand up at the lack of appreciation shown of his efforts—in a word, by acting as a lightning rod by which the heavy charge of electricity in the atmosphere is drawn off to one side and conducted harmlessly to the ground. It goes without saying, finally, that a consultant may be of very great service to the ignorant or incompetent physician. But, when all of these categories are set aside we remain with the one that I had in mind when this subject occurred to me: the men properly equipped with knowledge and experience who find themselves in presence of a difficult case not coming under the head of one of the more unusual specialties; under such circumstances, then, is there much likelihood of a consultation helping them out of their difficulties?

It is possible that opinions will vary on this score, on the ground of the traditional axiom that two heads are always better than one; but to this argument there is a ready reply: the whole affair depends on the quality of the heads in question, and I shall endeavor to show, farther on, that under ordinary circumstances the head of the consultant is not working at its best advantage by any manner of means. So far as I am personally concerned, the more extensive my experience has become the more open a question it is to me whether these consultations have any other merit than their moral effect on patient and entourage; I feel that if I myself were put to the test and forced to choose, I would rather place my reliance on one good, level-headed practitioner with the energy and time to buckle down to the case, than on any number of casual con-

sultants. There is also a side-aspect to this question that never seems to occur to the plutocrat. The only law that these people recognize and follow is that what they wish must go; what the other fellow is likely to think about it never enters into their heads, nor would it worry them much if it did. Now the constant demand for consultations on the part of the rich results in two things: (1) in wounding more or less the *amour-propre* of the regular adviser,—for it will never tend to increase the mental serenity of a good man who has put forth a special effort in a difficult situation to find his endeavors recompensed by scepticism; (2) in lessening the interest of the attending physician and in dividing up responsibility, for I will venture to affirm that never after the consultation-racket commences in a case is the medical man in charge as keen as he was before it.

I have said that I was doubtful as to the good of these consultations; but, bless you! if it were no worse than that! The trouble is that not at all infrequently they end in absolute disaster through the consultant's being entirely in the wrong. I have now seen so many and such gross errors made by the very best consultants that money could command that I really wonder that even the credulous public does not begin to prick up its ears. There is one man here in particular, concerning whom I can give no details, since to do so would be to designate him instantly, and I should be loath to do that, as he stands at the very top of his specialty and enjoys a well-merited reputation, with whom my ill-luck has been something phenomenal. I have seen him make mistake after mistake, and not little ones, but great, big errors; and of this I am absolutely certain, since years have since elapsed and the course of events has fully demonstrated that he was wrong. I have seen him walk right over a thing as big as a house without even suspecting its presence, or carry dismay into families by diagnosing cancer and tuberculosis when nothing of the sort existed, or tuberculosis when the trouble really was cancer. I am now referring to specific cases that occur to my mind. This sort of thing, when sufficiently repeated, rather dampens one's ardor; and yet, as I said above, this man's name is one of the greatest in the medical world.

After all, when you really come to consider this question, how could it well be otherwise than that these men should make mistakes? The big consultant is apt to be a man of sixty or over, who has all his life worked far too hard for any one individual, and whose existence, to put it plainly, is not very different from that of a prisoner condemned to the treadmill. He drags out his days in trying to sit on several chairs at once, with the well-known result that invariably follows that practice; yet his pride will not allow him to resign a single one of them, and his plight is rendered worse still by the almost universal practice in France of each physician attending to all his work alone, without partner or assistant. Such a man, for instance, will be professor at the Faculty, visiting physician or surgeon to the hospitals, and member of the Academy of Medicine and of other learned bodies, and will, in addition to all these calls on his energies, manage a more or less extensive private practice, besides writing a book now and then. He will start out by eight in the morning; see some cases, or possibly operate on a private patient before hospital hours; turn up at his wards between nine and ten and deliver a clinic and operate again, perhaps; race home to lunch, to be back at the Faculty in time for examination of candidates; return to his house again for office hours, and then attend the meeting of some Society or deliver a theoretical lecture at the Faculty—sandwiching in between all these duties other visits and consultations in different parts of the city when he does not have to go hours down into the provinces to see a patient there. How is it possible to expect anything of such a man? You have an appointment with him; he arrives on the gallop, late and harassed, conscious that he has other engagements ahead of him at which he is going to arrive later still; he is then farther irritated by the futile details to which the patient attaches such importance and by the idle theories propounded by the members of the family, who spare not an item and evidently think that theirs is the only client the poor man has to see in his day. Is it likely that any one driven in this manner is going to be able to really concentrate on your case or render you serious assistance? Is it a matter for surprise that, on seeing a difficult case one single time, without the possibility of studying it or of following its evolution, he should fail in his brief twenty or thirty minutes to straighten out a problem to which you have devoted in vain your best knowledge, reflexion and research for perhaps several weeks?

My personal experience, at any rate, in this matter has been disappointing, though other men may have fared better; but, in order that the latter may not think that I have been biased by exceptional instances, from which I have proceeded to unwarranted generalizations, I will endeavor to substantiate my thesis by two examples, which I consider to constitute the limit of possible things in the way of consultants' blundering. Into the particulars of the first of these it will not be necessary for me to enter, as its history was published with every detail in these columns on April 29, 1911. It was, in a word, a case of multiple myeloma, which during a period of nearly two years was seen by fully a score of physicians here, most of them excellent men, several of them consultants of the first rank, without one of them making the diagnosis. But the objection will of course be raised that this is an exceptionally rare disease, and one that appears to be practically unknown in France, and that it is unfair to draw inferences as to the utility of consultants in general from such an unusual occurrence as that. Granting, then, that this objection carries a certain amount of weight, I will proceed to give the details of my second example, which has never been published, and which is so perfectly extraordinary that I think it will shake the faith of even the most determined opponent. This second instance has in one way not quite the same value as the first one, unfortunately, in that I was not myself a witness of all its episodes. The myeloma case I followed personally from beginning to end, so that there is no possible doubt as to its incidents; whereas the following patient only came into my hands *after* the occurrence of the events that I am about to relate, so that I have had to go entirely by her own account of it. But from other points of view the second example is far more demonstrative, in that it concerned a very common disorder, lasted to our certain knowledge for nineteen years, and during that time was seen by a very large number of physicians. On account of this great length of time the patient's tale is naturally disconnected and deficient, and, for all the middle portion, altogether lacking in dates; but, in the main, it is manifest that her facts are

correct, and that the details and names that she does recall are all more or less to be relied on.

The case, then, was one in which a woman, with one renal pelvis filled with calculi and with constant hematuria, consulted many of the leading men in town *during nineteen years*, without one of them making the diagnosis; this duration is absolutely certain, for the patient knows exactly when her first hematuria took place, and also, naturally, when she met the surgeon who finally diagnosed the trouble and operated. This record of errors is not likely to be distanced in a hurry.

This lady, an American, now 47 years of age, was born in France and has always lived there. During her early years she had the usual disorders of childhood, including enteric fever. In 1874, at the age of nine, she underwent a rather startling experience, in that she was obliged to transship in midocean, at a moment's notice in the dark, in only a nightdress and peignoir; various rheumatic pains, from which she afterwards suffered for several years, were laid to this exposure. As a young girl she was always rather delicate, felt tired at the least exertion, and was subject to violent attacks of pain in her left flank, so severe as to cause nausea and to necessitate her retiring to bed. Her first hematuria did not occur until she was 25, but it seems fairly certain that these peculiar pains in her side were in reality nephritic colics; she says that they were quite a separate affair from the rheumatic pains previously mentioned. She married at the age of 21, in 1886, and had two children, in 1888 and 1890; there were no miscarriages. It was in the summer of 1890, shortly after her recovery from her second confinement, that she first noticed that her urine was stained with blood, without clots or pain; and she *positively affirms* that from that time until September, 1909, when she underwent operation, that is to say during nineteen years, her urine was never altogether free from blood, though its tinge would vary.

Her medical attendant at the time does not seem to have been much disturbed by this hematuria, and assured her that it was nothing of importance and would pass off. She was troubled with leucorrhea and metritis during that winter, and consulted a sage-femme about this condition in 1891. This woman, however, was not satisfied with her patient's general appearance, and turned her over to a well-known specialist here, an excellent man from every point of view. Incidentally, and to close this chapter of her history, she afterwards underwent local treatment at the hands of several gynecologists, two of them men of reputation, one of whom followed her case during an entire winter. But the story told about the first specialist, the man she saw after the sage-femme, is so remarkable that I have great difficulty in accepting it as it stands, for I know him well and am certain that he is the type of the conscientious, honorable practitioner. He is said to have had an analysis made of this red urine, and then, taking only into account the 2-3 gms. of albumen that it naturally contained, to have conceived a very pessimistic impression of the case, and to have told the family that it seemed to him a very serious matter, and one from which he doubted whether she would recover. He then put her on an absolute milk diet for upwards of a year, and in the spring of 1892 had a consultation with a confrère of excellent standing, the outcome of which was that the patient was advised to take a cure at Evian, where the local practitioner took an even gloomier view of the affair and informed the family that he did not think she would live three months.

One of the two children of the marriage died two months after birth, but the other one was in the meantime attended by a specialist who, when he withdrew from general practice in about 1895, recommended to the parents one of his younger friends, who became the family physician up to the time of the operation in 1909, consequently for about fourteen years. During this long period he did not come to any diagnosis, and every now and then a consultation would be arranged with some authority, the attending physician accompanying the patient on some occasions and not on others, the urine remaining constantly red and the side-aches reappearing now and then, though there were entire years when she would have none at all. So far as she can remember, at no time during all these years did she ever pass any solid concretions.

One of these consultants, a man who bears a very famous name indeed, is reported to have remarked, when the patient had finished giving her account of her symptoms: "Madame, votre récit manque absolument de vraisemblance!" and to have closed

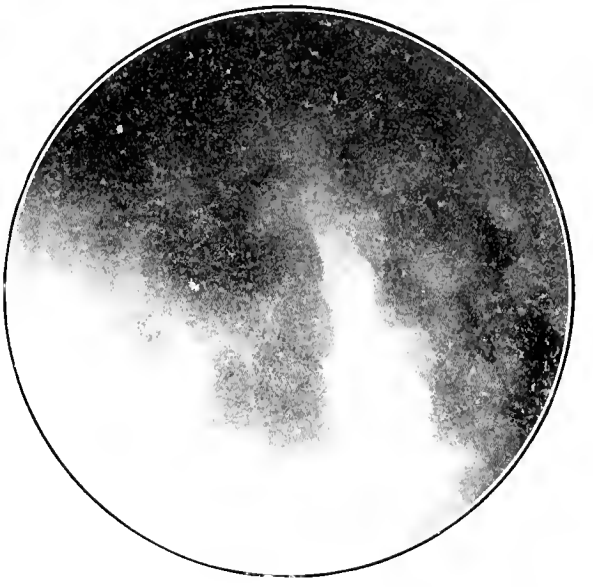

Fig. 1.—Skiagram of the left renal region from behind.

the interview by saying: "However all this may be, the case does not come at all within my province and you must see someone else." The dear man! if ever a case did come within his province it was that one! She also consulted a first-class specialist, an old friend of mine, very skilled in the use of the cystoscope, who is said to have reported that he could see blood coming from *both* ureters. Another famous and fashionable consultant is claimed to have told her frankly that he had no idea what could possibly be the cause of the trouble, and that he had never encountered anything like it. Still another renowned and very fashionable man took quite the contrary attitude; a little hematuria was not the sort of thing to scare him, and he had many ways of getting the upper hand of it; so that she remained under his care for quite a time while he experimented with a selection from his remarkable therapeutic armamentarium. During a trip she made one summer a prominent man at a German Spa was very pleased with himself at discovering that her right kidney was prolapsed; so he told her that that was the source of all her trouble, and had a bandage made to keep it in place. To the patient's mild

expostulation that the pains, when she felt them, were always on the *left* side, he replied that that was immaterial. The last eminent man whose counsels she sought seems really to have gone into the matter more thoroughly, though he was still as far wide of the mark as the others. He asked her whether she had ever lived in the tropics, wanted a blood-test made at midnight (filaria), and suggested a cystoscopic examination by a different operator; he finally gave her the address of a prominent surgeon, and advised her, in case the blood was really seen to come from *both* ureters, to do nothing, but, if from one only, to have an operation performed on that kidney (exploratory, I presume.

This closes, more or less, this long theory of consultants, all of whom seem to have been entirely in the clouds, and, however incredible it may appear, *no one of whom asked to have a skiagram made*, although during fully the last six or eight years before her operation this invaluable method of exploration was in current use! She is certain that in between times she consulted other physicians, but those that I have mentioned are all that made an impression on her. But, in the meanwhile, farther and more dramatic incidents had made their appearance. Thus she was suddenly seized one summer in the country—she cannot recall exactly when, but thinks it was quite a number of years before the operation—with a much more profuse attack of hematuria; a swelling rapidly developed in the left flank, the urine became very dark-red for several days, and she herself felt dreadfully exhausted from the loss, and experienced an awful sensation as of impending catastrophe. The same thing occurred a second time, in Germany, during the summer of 1909; profuse bleeding, although without clots, and fearful pain in the left side, worse than ever before. A third, final attack took place in September, about two months later, and the patient was then operated on *d'urgence*, as there was almost total suppression of urine, not more than 30 gms. in the 24 hours. For the correct diagnosis had at last been made in the spring of 1909, previously to the second severe hemorrhage in Germany, by an American surgeon in Paris, whose name I do not give, as I am not mentioning names, but whom every one *here* will recognize without further details. So soon as he heard the patient's story he asked to have a skiagram made, with the result seen in the first illustration that accompanies this article, and a short time later he had the great satisfaction of removing the remarkable collection of calculi represented in the second illustration. These calculi, eighteen in number, light café-au-lait in color when dry, about fill the hollow of the hand; they are all well flattened, weigh 55 gms., and the major diameter of several of the largest is 3 cm. Chemical analysis showed them to consist of granulations of uric acid englobed in a mass of tribasic phosphate of lime, together with traces of magnesia, each calculus having an outside coating of cystine.

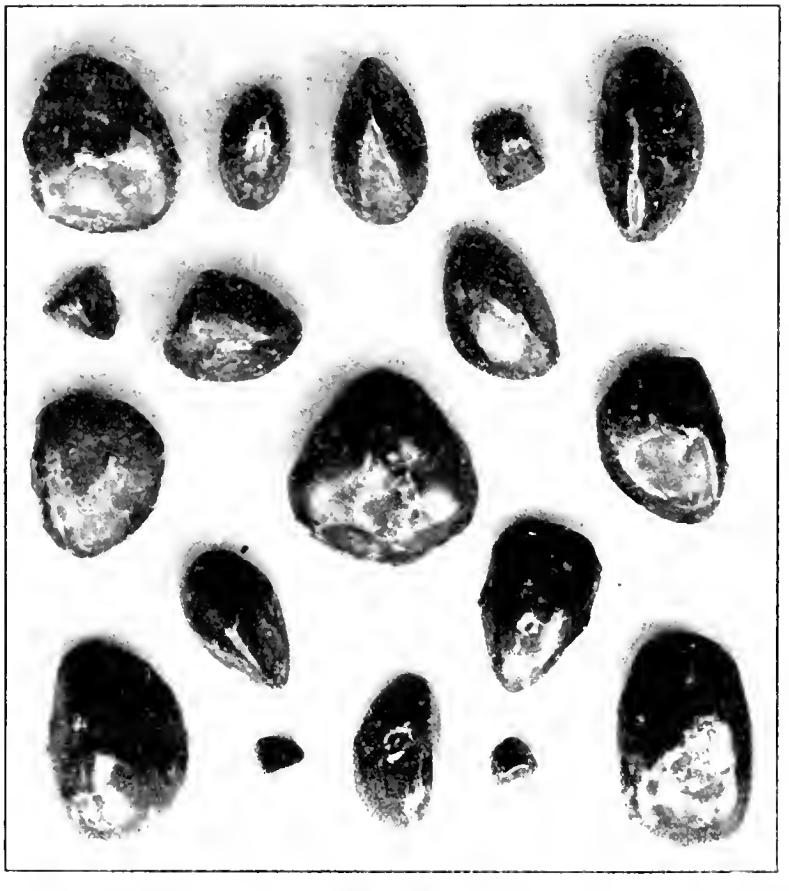

Fig. 2.—Calculi reproduced accurately in their natural size.

This, then, is the brief, though I am afraid necessarily incomplete and unsatisfactory, account of this remarkable series of blunders, which seems as though it must be almost without precedent. So near as the patient's memory serves her, the young surgeon who finally saved her life was the *twenty-fifth physician* whom she had consulted, not to count the queer folk, clairvoyants, homeopaths, and sage-femmes, of whom there were quite a series; and, when I add that this long list contains names that are recognized as authorities all the world over—it is really a pity that I cannot complete this tale by giving a few of them, but I am under promise not to do so—I think it will be admitted at all hands that this case does not reflect much credit on the leading representatives of the profession, as well specialists as consultants. Is it really, then, any wonder that, after the experiences that I went through with in my case of multiple myeloma, and after hearing of the vicissitudes of this second patient, I should be disposed toward pessimistic views, or that I should venture to place a mark of interrogation against the question of the practical utility of the distinguished consultant?

Glandular Fever.—W. H. Bowen reports a series of cases the main points of which were that they followed attacks of measles at varying intervals, they started as a cervical adenitis and periadenitis with variable fever, that the constitutional conditions were never severe, and that complete recovery occurred without any suppuration in any case. It seems probable that the measles prepared the soil and that a slight tonsillar inflammation led to the secondary glandular change. The chart of one of these cases showed three weeks of continuous fever, the temperature reaching 102° to 103° F. at the end of the second week.—*Proceedings of the Royal Society of Medicine.*

A SUGGESTION FOR AN IMPROVED METHOD OF USING RADIUM.*

By ROBERT ABBE, M.D.,

NEW YORK.

PARADOXICAL results are seen at times in the effects of radium, which challenge explanation. On superficial epitheliomata there is an almost uniform effect in causing retrograde change and usually a permanent cure. On the mucous membranes of the mouth and throat frequent disappointing effects follow its use, when the same dosage and time exposures are given as would be efficient on the skin. Sometimes a tongue cancer showing most luxuriant growth will yield almost to disappearance and then start up an extension as if it had not been touched. This transient improvement I have been inclined to attribute to the conquest of the secondary bacterial infection of the cancerous ulcer, but the lack of uniformity in action makes one discontented with this explanation. Even in large tumors elsewhere in the body, a considerable necrosis occurs about the applied radium tube, the more remote cells are often arrested and some parts stimulated. This uncertainty of time exposure, and distance, as well as the complicated problem of weak and strong specimens, makes the use of radium a constant puzzle to the uninitiated. Yet there is so much that is good and unique in its effect that even a small contribution will be welcomed by the growing number of those who have it to use.

The suggestions I have to make are in the direction of simplification. For ten years I have been on the lookout for cases where its use might be thought to have spread the disease. Such a suggestion was first made, I think, by Dr. Margaret Cleaves of this city from an experience in uterine cancer. I have seen a very small number of cases, like extensive cancer of the maxilla or the tongue, where its use was admittedly experimental, in which it seemed to me the disease progressed more fiercely after a brief respite, but these cases of advanced disease often take on this action without any treatment, so that I have been rather unwilling to argue from them. Nevertheless the demonstration has been made that, while radium electrons retard growth and finally kill the life of seeds, there is a stage of dosage, as one may call it, where plant life is stimulated. In all my early experiments with seeds, planted after exposure to radium, an illustration of which I showed to this society some years ago, I saw only this life-destroying action.

During the last summer I demonstrated, by two very complete methods, the stimulating effect of radium, and in this fact, I suspect, lies the solution of the problem of its use, at least in part. The stimulation of growth depends on the time exposure, the distance, and the kind of rays used. I believe we may assume the biological acts of living cells to be the same, whether animal or vegetable.

In these experiments I used oats for the first time, because of their rapid growth. In four weeks an oat may grow about one foot high. One hundred milligrams of pure radium bromide in fine glass tubes was placed in a bottle with two tablespoonsfuls of selected oats. To prevent inequality of action the bottle was strapped to the axis of a diminutive water wheel rigged up to run by a faucet at an even revolution, so that every oat was in turn brought in contact with the radium thousands of times during the two days exposure. At certain intervals I removed twenty-five oats and labeled them. At the end of two days I planted them in rows in special sifted soil and raised them first under glass. Alongside of them, under similar conditions, a row of unradiumized oats. The result at the end of four weeks is shown in this photograph. The plants were cut at the roots, tied in bundles, measured, and weighed. Compared to the normal growth, three bundles were above the normal, and three below, both in height and weight. (See Fig. 1.)

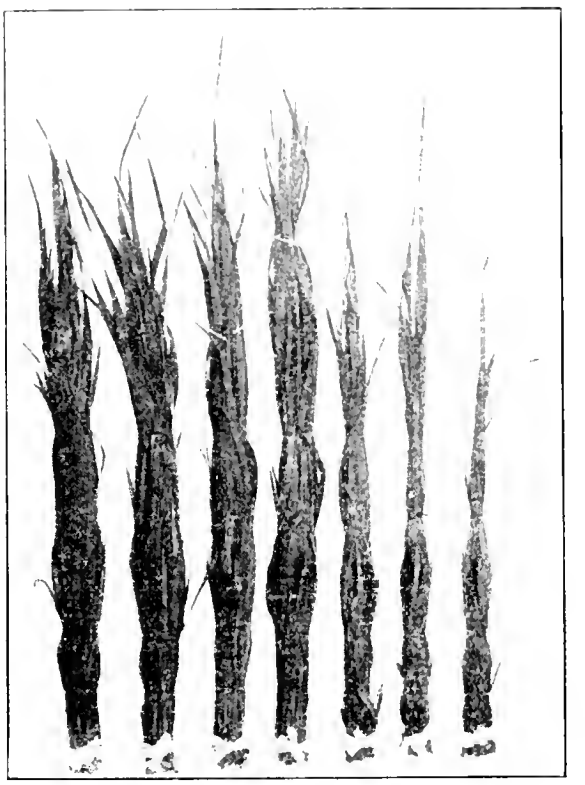

Fig. 1.—RESULTS OF EXPOSURE TO RADIUM

		STIMULATED			DEPRESSED		
Time Exposed	No Radium	2 Hours Radium	8 Hours	16 Hours	24 Hours	36 Hours	40 Hours
Height	100	111	107	111	84	71	53
Weight	100	111	120	116	48	44	32

The interpretation of this experiment is this: A deterrant effect on cell growth depends on time exposure, and must be a definite equation for every specimen of radium. The main value lies in the demonstration that, on seeds as well as tumors, the electrons may produce detrimental results, as well as mysteriously beneficial ones, and that probably all the beautiful effects so often seen result, in a measure, from accidentally correct time exposure. It is evident that the oats were alternately near and far from the radium tube, as they whirled about, so that twenty-four hours of exposure in the bottle would only represent part of an hour of close contact, such as takes place when radium tubes are applied on tumors.

A second experiment was, therefore, necessary to show the persistent action of radium at a fixed distance.

This was made as follows: (Fig. 2.) A series of twenty little shelves of mosquito netting, one-fifth

*Read at a meeting of the Practitioners' Society, November 3, 1911.

of an inch apart, were arranged by cutting a square hole in the center of thin boards laid on top of each other with netting sandwiched between. On each shelf were placed twenty-five oats, and a Wickham plaque of naked radium (25 mg.) was bound on top

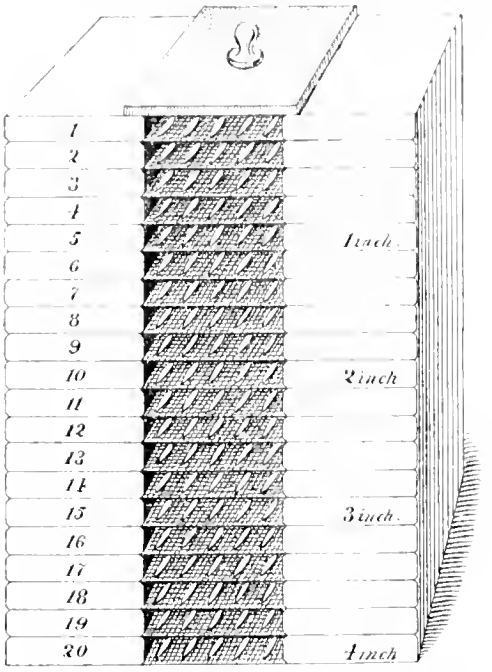

Fig. 2—Twenty shelves of mosquito net, each holding 25 oats; at the top is a plaque of 25 milligrams of naked radium.

of all, so that each shelfful received a given bombardment of radium at a uniform distance during a similar period. In this experiment I was also able to test the efficiency of all the combined rays emitted from naked radium compared with former work where the alpha rays are suppressed by the glass container. The exposure of these seeds was continued for six days with frequent shaking to change the exposure of all the oats on each shelf. The mosquito netting would offer no barrier to the alpha rays, which even tissue paper would have suppressed. This series was planted in twenty rows an inch apart, with two additional rows of unradiumized oats for comparison.

The results were more interesting than I had anticipated. The two rows nearest the naked radium, but not in contact, were one-fifth and two-fifths of an inch from it. They all germinated and tried to sprout, but died, before they were an eighth of an inch high, during the first week.

Those in the third row were now up 2 inches; the fourth row, 3½ inches; the seventh to the eleventh rows were outdoing all but the normal ones, which were 5 inches. At the end of four weeks the fourth, fifth, sixth, and seventh rows—which had been 1 to ½ inch from the radium—were now the finest of all, even exceeding the unradiumized rows, notably of a rich growth, darker green in color, and 12½ inches high. All plants were now cut at the roots, tied, photographed, measured, and weighed. (Fig. 3.)

Let us first remember that the seeds had been continuously played on for six days by a discharge of all the electrons issuing from the naked radium. Let us recall that alpha rays are known to be of slight penetrating power, of short area of travel, and subject to change into other rays.

The beta rays have relatively feeble penetrating power, and carry charges of negative electricity. The physics of these rays are credited with soft and hard qualities, the former of feeble penetration, the latter going deeper into the tissues. The gamma rays, swift, ultra-penetrating, of negative electric charge, are probably the ones more efficient in all use of radium in glass or metal containers.

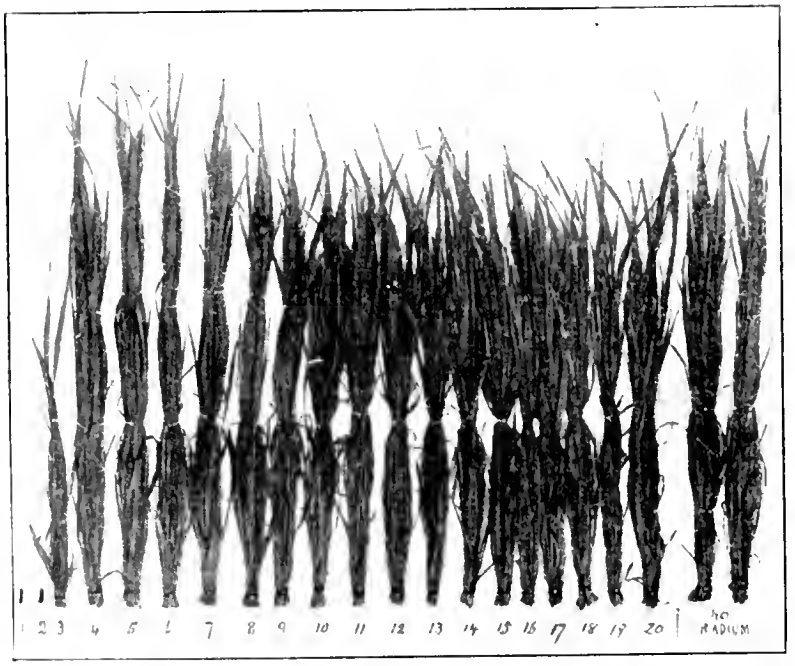

Fig. 3—Growth of oats, exposed to naked radium at distances from ¼ to 4 inches. Twenty rows. Two rows for comparison, without radium. Exposure six days. Growth after planting, one month. Nearest two rows killed. Fourth, fifth, sixth, seventh, stimulated. Beyond seventh (1½ inches) all retarded. The nineteenth most stunted of all.

The interpretation of the experiment on oats at fixed distances from the radium shows that the nearby cells, up to half an inch distant, were all killed. These had the combined rays, but, above all, were exposed to the alpha.

The seeds at distances from ½ inch to 1½ inches were greatly stimulated beyond normal growth. These had the combined beta and gamma rays, as well as any secondary ones emanating from the decay of the short alpha rays.

The seeds from 1½ to 4 inches were depressed in their growth, but singularly enough not in inverse ratio to their distance, as would be the case were the energy a losing one as the distance grew greater, or as it might be considered if it had lost by absorption in nearby seeds. On the contrary, the more distant seeds were most affected, so that from 1½ to 4 inches the growth represented by size, weight, and color of the plant showed most injury at the farthest end, the weakest plants being on the

nineteenth row, or about 4 inches away. One may interpret this phenomenon as he wishes, but as I had elaborately thought out the experiment to secure fair play for each seed in choice, planting, soil, moisture, nurture, sunshine, etc., I must attribute the inequality of growth to only one cause—radium

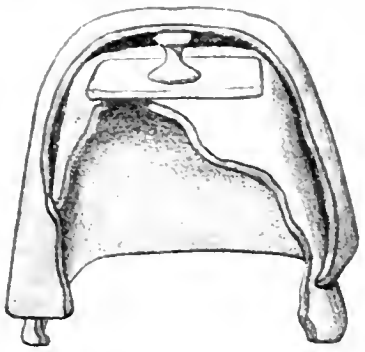

Fig. 4.—Lead device with lead cover for supporting the radium plaque at a proper distance above the diamond surface. (Partly cut away to show the interior.)

I am inclined to ascribe an irritating and stimulating quality to the alpha and soft beta rays, and a destructive force to the deep, penetrating, hard beta and gamma.

The twenty shelves of oats should represent twenty corresponding sections of a tumor subjected to the same experiment.

The importance of this experiment to me is the corroboration of the work of French observers, notably Wickham, that the best results have been obtained by enveloping a heavy charge of radium in lead of from 1/10 to 2 mm. thick, which suppresses the burning alpha and soft beta rays.

On this practice I have seen during the two years past some of the most hopeful results.

It has been a serious handicap that, in order to obtain massive doses of radium, one had to risk severe burning of the skin, so that, except for superficial growths where destruction by all rays combined was desired, one had to withhold the full value of the deep penetrating gamma rays in curative doses. Nevertheless one can demonstrate by photographic plates, laid upon the abdomen when a rectal or uterine application is made, that a strong discharge does penetrate the entire body, though this represents less than one wishes of these rays, while their burning effect prevents a longer use of them in the deeper parts.

If however, by suppressing the short, irritating, and burning rays one can apply big doses of rays to uterine and other internal cancer with benefit by enveloping the radium in heavy lead, or if on surfaces one can reach subcutaneous recurrences by distance applications without severe dermatitis, we have gained appreciably in its use. Such, it seems to me, is the present position of technical work.

I have certainly seen the best results since using thick lead filters, as advised by Wickham, and now am watching with amazement and pleasure the melting away of superficial recurrences which one can not successfully extirpate.

In some of the nodular subcutaneous and lymphatic recurrences about scars of mammary amputation we certainly see rapid disappearances, without dermatitis, by lead-protected radium application.

Perhaps we may hope by the logical extension of its use along the line suggested by the foregoing experiment to reach many of the parotid, deep thyroid and other glandular tumors, now inaccessible.

I illustrate herewith (Fig. 4) a simple device which I find most efficient in carrying out the above ideas. Exposure of the skin for one hour or of diseased masses for several hours is thus practicable. It is notably useful in evenly applying radium rays to large surfaces of nerves, lupus erythematosis, lichen planus, etc., thus avoiding the uneven scarred appearance of otherwise fine cicatrices, where radium has been applied in tabes.

PEDIATRIC MEMORANDA

TUBERCULOUS PERITONITIS. SARCOMA OF THE KIDNEY.

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK.

The large abdomen of infants covers many diagnostic sins. Being quite common in early childhood, especially in association with intestinal indigestion and rickets, it is rarely taken seriously, so that grave intraabdominal affections are frequently overlooked or detected at a time when therapeutic measures are no longer available. This is certainly often true in the group of cases I am about to describe.

Fig. 1.—Tuburculous peritonitis

Tuberculous Peritonitis.—The fifteen-months-old little girl (see Fig. 1) was quite small and delicate at birth. Her father was suffering from pulmonary tuberculosis and had to leave home for the country when she was but a few months old. At about that time also she was taken off the mother's breast and put on cows' milk mixtures. She remained pale and puny, and was frequently subject to indigestion and "colds." Her abdomen was always

greatly distended, but received no particular attention, since, as the mother frankly put it, "every baby she knew had a large stomach." The many physicians she consulted apparently agreed with her views, for the treatment ordered was principally dietetic. When through the courtesy of Dr. Louis B. Sachs the little patient came under my observation at the hospital her abdomen was unusually voluminous and tense, barely compressible, and presenting considerable difficulty to reveal its contents by palpation. Although the parental tuberculous history strongly tempted the assumption that the child was afflicted with tuberculosis, either of the intestines or peritoneum, I refrained from committing myself to such a diagnosis, fully realizing that chronic abdominal enlargement only too often is the result also of nontuberculous enlargement of abdominal organs by neoplasms and otherwise, rachitis, congenital or acquired megacolon, ascites, and even simple indigestion. My hesitation to make a "snap-diagnosis" was amply justified a few days later, when, contrary to our expectations, the von Pirquet tuberculin reaction proved negative and several other characteristic "text-book" symptoms of tuberculous peritonitis, such as persistent diarrhea and colic, progressive emaciation and involvement of adjacent lymphatic glands, failed to materialize. Hence, with the meager symptomatology in view, there was nothing else left for me to do but to endeavor to arrive at a correct diagnosis by exclusion. As we gradually gained the good will of the little patient and she more placidly submitted to a more searching examination of her abdomen, we were soon enabled firstly to eliminate enlargement of the liver, spleen, and kidneys and tumefaction of the intestines, and, secondly, to detect an exudation within the abdominal cavity. Furthermore, we also learned that her temperature was almost invariably one or two degrees above normal, notwithstanding careful restriction of the diet and thorough intestinal cleansing. We thus had three well defined symptoms to base a diagnosis upon, *i.e.* an unusually large abdomen, free fluid within its cavity, and irregular fever—which in my opinion were ample to pronounce the case as tuberculous peritonitis, even though the tuberculin reaction proved negative. I promptly referred the patient to the surgical division for operation. The laparotomy very skillfully performed by Dr. A. Sturmdorf revealed the presence of about a pint of serofibrinous fluid in the abdominal cavity, firm adhesions between the peritoneum and omentum, and free distribution of small tuberculous nodules along the inflamed structures. The small abdominal incision healed by primary union within a few days and the patient made a perfect recovery soon thereafter. As far as I am aware she has remained well since.

Sarcoma of the Kidney.—Unfortunately such beautiful results are almost never obtained in malignant renal neoplasms, even if detected and operated upon early—which is so rarely the case! As a rule, they reach the consultant at a time when they are at death's door, when the growth, as it were, stares him in the face, and treatment, operative or otherwise, is utterly useless. I believe that the many failures to recognize the condition early, to a great extent, are due to faulty teaching of the symptomatology of the disease. Text-books often speak of hematuria and cachexia as pathognomonic symptoms of malignant renal growths, while, as a matter of fact, they are of little diagnostic value.

In the first place, blood in the urine may be detected microscopically only in the incipient stages, when the renal pelvis is still free. For as the tumor assumes great dimensions, the kidney degenerates and the ureter becomes occluded, so that the urine obtained for examination—coming as it does from the unaffected kidney—is entirely free from abnormal constituents. Secondly, hematuria is much more commonly characteristic of renal or vesical tuberculosis, hemorrhagic nephritis, purpura, and the like. Now, as regards the cachexia, it very rarely sets in prior to the last stages of the affection, *i.e.* at a time when the tumor can readily be palpated and hence the diagnosis established without much ado. Indeed, after a moderately extensive experience with these cases I am inclined to the opinion that the presence of the tumor—as demonstrable by palpation or also with the aid of the Röntgen rays—is the only reliable sign of renal neoplasm, and should always be looked for in children irrespective

Fig. 2.—Sarcoma of the kidney.

of the other affections they may be suffering from, more particularly when they give a history of arrest or loss in weight, persistent abdominal pain, and chronic intestinal indigestion without any apparent cause. These were the only early symptoms in the four cases of kidney tumors I reported on former occasions,* as well as in the case under discussion. This patient was 23 months old when it came under my observation. After the growth had reached a large size he was seen by several eminent clinicians in the city and the mother was thoroughly familiar with the diagnosis and prognosis of the case. Still she had some hope left that some one would perform a miraculous cure, especially with the "new blood medicine"—the daily press was at the time filled with exaggerated accounts of the marvelous cura-

*"Modern Diagnosis and Treatment of Diseases of Children," 1911, and *Jour. of Dermat. and G. U. Dis.*, Vol. XV, No. 5.

tive value of the mysterious 606, which has since proved a most prolific source of affluence to the keen professional quack. The history of the case was negative. The parents were in good health and had four additional, robust, older children. A mere glance at the child's abdomen (see Fig. 2) was sufficient to determine the presence of a large growth within it, but as it occupied the entire abdominal cavity, pushing every organ out of its way in its spread across from the right to the left side, it was next to impossible to trace its exact origin. The intense intraabdominal pressure upon the large blood vessels produced marked edema of the lower extremities and genitalia, and owing to displacement of the intrathoracic organs the lungs were congested, the breathing was very difficult, and the heart's action rapid and irregular. The patient was finally relieved of his agony about three weeks later.

Although a religious Hebrew the father permitted me to make a post-mortem four-inch incision in the right lumbar region, through which I was enabled to learn that the tumor originated from the right kidney, was very irregular in outline and firmly adherent to the adjacent structures, approximately between five and six pounds in weight, and of mixed hard and soft consistency, the hard portions predominating. Whether an early operation would have saved this child's life is, of course, problematical. As renal neoplasms in children are usually congenital and can readily be diagnosed within a few months after birth or earlier, it is imperative to recommend an operation immediately, if possible before secondary metastases have formed in the neighboring structures, and the uninvolved organs have become embarrassed in their functions.

127 West Eighty-seventh Street

SOME POINTS IN THE DIAGNOSIS AND TREATMENT OF INTRANASAL SUPPURATION.

By JAMES DONELAN, M.Ch., M.B.,

LONDON.

CHEVALIER OF THE CROWN OF ITALY, LARYNGOLOGIST TO THE ITALIAN HOSPITAL, LONDON, AND TO THE LONDON OPERA HOUSE, ETC.

The subject of intranasal suppuration is a very large one, and I shall therefore select only three of the diseases in which this symptom shows itself. These are selected on account of their common occurrence as well as of the more than usual importance of securing the earliest possible diagnosis so that no time may be lost in adopting the most efficient treatment. The diseases selected are: (*a*) Tuberculosis of the nose, (*b*) nasal syphilis, and (*c*) chronic suppuration of the accessory sinuses.

Tuberculosis.—Tuberculosis is here understood to include or rather to be pathologically identical with lupus, though on account of certain differences in the mode in which this disease manifests itself clinically it is convenient to preserve the terms lupus and tuberculosis. Moreover, the occurrence of any other form of tuberculosis than lupus in the nose is so rare that it may be looked on rather as a pathological curiosity than as something to be distinguished in the diagnoses of every-day practice.

We see almost without exception the slowly advancing lupus, certainly nothing at all comparable to tuberculosis as it occurs in the larynx. Whether this is entirely due to the greater resistance offered to an identical organism by the physiological defenses at the respiratory entrance or that lupus is always due to a less active form is a point much debated. It is at any rate remarkable that the deeper the lesion of the respiratory tract manifests itself the more rapidly progressive it is. Thus in the lungs we are always justified in classing the disease as tuberculosis, in the nose and nasopharynx very rarely so, while the larynx seems to occupy clinically as well as anatomically a middle position and may distinctly manifest the clinical signs of either, tuberculosis being far the more common form.

The usual point of attack is the lower anterior part of the cartilaginous septum just inside the vestibule, the floor, or the anterior end of the inferior turbinal. This septal seat of election may be determined by habits of picking the nose causing direct infection or because it is the point most exposed to the incidence of the air-stream to a degree varying with the form of the nostril in different individuals. On the septum it sometimes shows itself as a small sessile, reddish-brown or raspberry-like tumor, or it may be seen at a still earlier stage as a number of tiny scattered points of similar aspect. These latter are difficult to distinguish from the surrounding tissue, but may be "brought out" by use of adrenalin and cocaine. They may form multiple nodules or may coalesce into one, but in any case they are characterized by their tendency to ulcerate, break down, and perforate the septum. On the floor and turbinal the tendency to break down and ulcerate is not so marked. Respiratory obstruction varies with the degree of inflammation and the amount of pus and crusts. The pus has a faint, sour, unpleasant odor without the stench of ozena or syphilis. On clearing away the secretion it is found not to recur readily. If perforation of the septum has taken place the outline of the hole is irregular and serrated and surrounded by pale, pink granulations. The bony septum remains unaffected. There is no falling in of the nose, but where the tip is unaffected exteriorly it is often drawn down tightly by retraction of the cicatrices as the disease tends to heal in some places while advancing in others. The course of the malady is very slow and usually painless. The discharge is but little noticed until smell becomes perceptible to the patient or his friends or the constant formation of crusts annoys him.

Other points to remember as regards the diagnosis are that the disease most often occurs between puberty and thirty years and is twice as common in women as in men. It is distinguished from congenital syphilis, for which it is most frequently mistaken, by the absence of the pain so common in syphilis, especially at night, as well as by the immunity from bone disease and marked fetor. The very slow erosion of the tissues is also in marked contrast to the rapid destruction of syphilis. In doubtful cases von Pirquet's skin reaction should be sought for or antisyphilitic treatment may be tried. In the large majority, however, the presence of lupus nodules on the adjacent skin or of signs of infiltration or cicatrization in the nasopharynx or larynx will help to confirm the diagnosis.

The most reliable method of treatment in early cases is the careful use of the electrocautery at intervals of a week or ten days. It should be applied under local anesthesia around the margins of the

advancing ulcers and broken down nodules. If one is fortunate enough to see the case in the stage when there are only minute points of infection on the septum or elsewhere a fine cautery point at a cherry-red heat should be inserted into each. In the absence of the electrocautery chromic acid may be tried, but its action is scarcely intense enough to secure destruction of the infected tissue without unnecessary damage to the yet unaffected parts. After cauterizing nitrate of mercury ointment in soft lanolin or vaseline in the proportion of 1 in 8 or 1 in 10 should be applied daily during healing. If, however, the disease is already deep and extensive no time should be lost before thoroughly curetting the infected tissue under general anesthesia. Lupus is very apt to recur and cases should be kept under observation while measures to improve the general tone and vitality and especially to overcome the usually associated anemia are carried out. In this connection arsenic is perhaps the most reliable medicine. Some consider it almost a specific for the disease, but too much should not be expected of it. Tuberculin may also be tried, but experience up to the present has not been generally satisfactory. The same may be said of Röntgen rays and the Finsen light, however useful they may be in lupus of the skin. There is no doubt that if the case has been diagnosed sufficiently early, and especially if treatment has been begun before infiltration of the deeper parts has taken place, it can be cured. Where, however, deep infiltration has occurred the prognosis is more doubtful and even after the most energetic and careful treatment these cases should be kept under regular observation as quite new infiltration of previously healthy tissue may unexpectedly show itself. Though healing may take place in one place while the disease advances in another, there is no tendency to the spontaneous healing one often sees in the larynx.

Syphilis.—Suppuration in the nose may be also due to syphilis in some of its stages. As a rule, there is very little purulent secretion from the rare primary nasal chancre, though there may be a good deal of watery discharge when it ulcerates. At the same time mucopurulent discharge may accumulate in considerable quantity in the inferior meatus. This, however, does not readily recur when wiped away and is shown to be scanty and inoffensive in character. The diagnosis is often difficult and in persons over forty years of age has to be distinguished chiefly from malignant disease. The effect of mercury and potassium iodide is, it need scarcely be said, a most reliable as well as convenient criterion, but recourse may be had to Wassermann's reaction or the microscopic search for spirochetes.

Secondary nasal syphilis is attended merely with coryza, which is distinguishable from ordinary coryza only by its duration. Mucous placques may be observed on the septum and turbinals, but if pus be present it is not due to the constitutional infection at this stage. It will be more likely the result of coincident suppuration from other causes in some of the accessory cavities.

It is the tertiary stage of the disease that has chiefly to be taken into account in considering cases of nasal suppuration. Tertiary syphilis may show itself at first in one of two forms in the nose either as a gumma, usually on the septum, or in the form of diffuse gummatous infiltration. Both forms are liable to go on to ulceration with perichondritis, periostitis, and necrosis. It is rare to have the opportunity of seeing the dark-red resistant swelling on the septum produced by a gumma before it has broken down. Discharge and crusts usually fill one or both nasal passages. Careful inquiry will often bring out the point that there was a good deal of pain, especially at night, about the root of the nose before any discharge took place and that pain has been much less frequent since pus appeared in the nostril. On removing the accumulated secretion the irregular ulcer can be seen. The edges may be sharp cut or excavated and the floor is flat and covered with tenacious yellow matter, the degree of erosion varying from a single ulcer to the most extensive destruction of not only the nasal structures, but of those adjoining. If the nose has been regularly cleansed and the cartilage alone is affected the discharge is not specially offensive. The disease, however, unlike lupus goes on to attack the bones and then the discharge becomes horribly offensive. At close quarters the ozena of a neglected atrophic rhinitis may seem worse, but it has not the carrying power of that of tertiary syphilis. Necrosis may be looked on as the most characteristic sign of intranasal syphilis as there is practically no other disease in which it occurs. A swelling on the hard palate is often the first visible sign of necrosis low down on the vomer which could not be seen through the nasal passage as, for instance, owing to the projection of a deflected septum. The probe will detect bare cartilage, bone, or loose sequestra. The only things a sequestrum could be confounded with are a rhinolith or a foreign body. Sometimes the ulceration may closely resemble that of lupus, but in the latter there is no necrosis of bone and the effect of antisyphilitic remedies will settle the question even if no assistance is given by evidence of syphilis in other parts, while in the case of lupus external signs are rarely absent if the intranasal disease is at all advanced. There is only one treatment, namely, that by mercury and iodides. Mr. Colles of Dublin, who described Colles' fracture and who had an immense experience of syphilis, used to say in his clinical lectures: "Gentlemen, in syphilis the mineral is always useful." By the mineral he meant mercury. It is best given in the form of inunction and with ordinary precautions it is quite possible to carry out a most efficient inunction course without interfering with the avocations of the patient. I am told that at certain Continental centers where mercury is extensively used not merely as a simple and effective mode of treatment, but apparently for the exhibition of a most impressive ritual, it is thought necessary to have the inunctions done by a masseur, who is also a trained athlete. For my part I have never known a patient who could not easily produce the full physiological effects of the drug by his own unaided efforts. As a matter of fact, the precautions have to be against salivation occurring. At the hospital with which I am connected I have for a long time treated out-patients by means of inunctions. The patient is instructed to take if possible a warm bath and then to rub well into his groins and lower part of abdomen about a drachm of blue ointment on alternate nights, on the other nights he rubs the same quantity into his arm-pits. He sets apart a special set of underclothing to wear at night while carrying out the treatment. In the morning he washes off any external traces of the ointment. He is instructed as to the signs of salivation and to cease the treatment and report himself without waiting for the end of the week usually

prescribed. At the end of the week in most cases considerable improvement has been effected and salivation has not occurred. A mixture containing mercury, various idodides, and sometimes arsenic is then ordered for a week and the following week the inunctions are resumed either daily or on alternate days, according to the progress of the case. As many as 100 inunctions may be given in this way without other than beneficial effects. It is not within the scope of this lecture to go fully into the treatment of syphilis, but these hints based on a long and pretty extensive experience may have some practical value. A word or two on the use of salvarsan, or 606, may not be out of place. I have had the opportunity of using this new remedy in hospital and private practice in some twenty-five cases. Certainly the rapidity of the improvement in the symptoms is often very remarkable, but there appear to be no grounds yet for thinking that the results are permanent, while we have had only too many instances recorded of deaths from acute arsenical poisoning, heart failure, etc.—I believe some forty-two up to the present date. I was much struck with what Professor Neissner said in a recent lecture in London on this subject, that in mercury we had an efficient and safe remedy for syphilis and that it had been demonstrated over and over again that the disease could be safely cured by it. The experience already accumulated would seem to show that recourse to salvarsan should be had only after very careful consideration with the clearest possible explanation to the patient of the attendant risks and then only in those rare cases in which mercury is not tolerated in any form.

Chronic Suppuration of the Accessory Sinuses.—We now pass to the third, and on account of its prevalence, especially in chronic forms, the most important of the causes of intranasal suppuration we have to consider in this lecture.

Acute sinusitis need not detain us long. It is seldom that the symptoms are distinguishable from those of an acute coryza except in the case of the maxillary antrum. If there are neuralgic pains about the head with a unilateral flow of pus or mucopus from the nose there is probably inflammation of an accessory sinis; a bilateral flow is not so likely to be due to sinusitis. The pus may not appear in the nose in the case of patients who have taken to bed on account of acute coryza, but in these cases it may often be detected flowing down the back of the pharynx. As a general rule, these acute attacks do not come under observation as they so often end in spontaneous cure. Besides the neuralgia, headache, and presence of pus in the nose inflammatory swelling of the middle turbinal is one of the most certain signs of sinus inflammation. In the case of the posterior ethmoidal cells and sphenoidal sinus this is not so marked as these discharge over the convex septal surface of the turbinal, but where the frontal, anterior ethmoidal, or antral cavities are involved the looser mucous membrane on the concave exterior aspect of the turbinal becomes enormously swollen so as to block up the middle meatus and sometimes even to such an extent as to give the middle turbinal the appearance of being double. There will also be some tenderness on pressure over the superficial sinuses when these are involved, with sometimes lacrymation, intolerance of light, and usually a sudden rise in temperature with perhaps a rigor. The treatment consists of measures to alleviate the pain and hasten the discharge of the accumulated secretion or pus. The patient should be kept in bed or at any rate in a warm room. Pain is best relieved by warm fomentations and inhalations containing menthol or friar's balsam. A useful formula is 10 grains of menthol in an ounce of rectified spirit, of this a drachm to a pint of water at 140° F. should be inhaled for from seven to ten minutes from an inhaler in which the air is drawn through the medicament and not through a sponge, or a drachm of compound tincture of benzoin may be used in the same way in the inhaler. The nasal douche should not be used in acute sinusitis. Adrenalin or cocaine or a combination of both may be used in spray to diminish congestion and facilitate discharge. Most cases get well on this line of local treatment combined with general measures to reduce fever and promote metabolism. In a few resolution does not take place, and there may be danger of chronicity or threatenings of orbital cellulitis or of cerebral trouble. In these the question of operation may at once become urgent. When the antrum of Highmore is affected the slight operation of puncture and washing out by means of a trocar and cannula may be performed at once if the symptoms are severe, and this may be repeated with benefit several times. Occasionally the frontal or orbitoethmoidal cells may point externally, threatening the orbit, or the frontal inflammation may cause symptoms of meningeal irritation. In such cases the cavity concerned should be opened without delay. No radical operation should, however, be attempted in the acute stage, and this rule applies to exacerbations of chronic sinusitis. It will be best to merely open the affected cavities and enlarge the drainage through the nose, leaving the skin around open until the acute symptoms have passed off. The tendency to chronicity is chiefly determined by the size of the outlets of the various sinuses. Repeated attacks of coryza with suppuration may have little or no effect in causing chronic suppuration in the superior sinuses, frontal, ethmoidal, and sphenoidal, as long as the discharge can flow away freely. On the other hand, in persons in whom the nasal passages are cramped either from hereditary influence, neglected adenoids, chronic rhinitis, and so forth the danger of chronicity is very much greater, and even a single attack of sinus inflammation may eventuate in chronic suppuration.

Chronic sinusitis is much more common than may be supposed, and has been found in from 30 to 40 per cent. of all bodies examined post mortem by various investigators. Evidence of chronic suppuration is found more frequently in the maxillary antrum than in all the others taken together. In considering any case of chronic intranasal suppuration the first thing to do is to ascertain whether the antrum is the site of the disease. Next the anterior ethmoidal cells, then the frontal, the posterior-ethmoidal cells, and the sphenoidal sinus, though this order of frequency of attack as regards the smaller cavities is variously put by different observers. It is not proposed here to give a complete account of the general and local symptoms, which can be found in any text-book, but I should like to call attention to some points connected with them that are of importance. Nasal obstruction, occurring for the most part early in the day, and discharge from one or both nostrils are mostly complained of. Swollen mucous membrane, granulations, and polypi in the middle meatus are almost pathognomonic of suppuration in the cavities draining into the hiatus semilunaris: maxillary antrum, anterior ethmoidal cells,

and frontal sinus. Polypi are, however, more frequently associated with frontal suppuration. The amount of discharge, especially in this region, affords no reliable information as to which cavity may be affected. Another point that is made much of in some text-books is that suppuration from the frontal sinus appears more anteriorly in the hiatus semilunaris than when the antrum or ethmoidal cells are engaged. This is not borne out by universal experience, and a moment's consideration of the innumerable slight variations in the form of the confluence of these outlets will at once show how unreliable the direction of the final flow may be as an indication of its remote source.

Cacosmia Subjectiva is often, but not always, complained of; neither is the sense of evil smell always subjective, but may be perceived by others, though not at such a distance as that of atrophic rhinitis or syphilis. In late years more and more attention is being given to the ocular symptoms which so often arise in connection with sinus trouble. Apart from inflammatory lacrymal and conjunctival affections which chiefly arise in connection with acute sinusitis, there may be reflex troubles such as photophobia of intermittent character, keratitis, asthenopia, in various forms, iritis, and most frequently optic neuritis. This last has been found associated with more than three-fourths of the cases in which sinus trouble was present. Eye troubles should therefore always suggest a careful examination of the nose and nasopharynx, as many of these patients may have been swallowing discharge from the sphenoidal or other cells for years without being aware of it. As a rule there is little pain associated with chronic sinusitis, but when headache, faceache, or neuralgia are present they often proceed from an exacerbation of the inflammation and should suggest a rhinological examination.

In conducting the local examination, the first thing is to gently remove any secretion that may be present in the nose by means of cotton-wool pledgets. The next point is to note whether it recurs immediately and where. The discharge of lupus and syphilitic rhinitis recurs as a rule but slowly, and may be regarded as an oozing rather than as a flow. The site of recurrence should also be noted. If on the septal side of the middle turbinal the pus probably comes from the sphenoidal or posterior ethmoidal cells, though it may come from the maxillary or even the frontal in case there is an accessory opening to the antrum and the latter may be acting as a receiving chamber for discharge from a frontal abscess. Pus in the middle meatus, especially associated with swelling of the surrounding mucous membrane as already mentioned, is most suggestive of suppuration in one or more of the anterior group of sinuses. Whether pus is seen or not, what is known as Fraenkel's test should now be applied. The patient's head is bent forward between his knees and rotated so as to bring the suspected side uppermost. When the nose is again examined pus may be found in the middle meatus, and this is evidence that whatever its exact source it comes from one of the anterior group.

Transillumination may next be tried, but is so very unreliable, from various causes connected with the bones, the lining membrane, the light itself, or the intelligence of the patient, that its chief use appears to be to occasionally afford an interesting corroboration of evidence that can be obtained with more certainty by other means. It is fortunate that while the maxillary antrum is the cavity most often affected it is also that which can be most readily and conclusively examined. The methods consist in exploratory puncture of the nasal wall through the alveolus or through the canine fossa. The first is the method now generally followed. The inferior meatus is thoroughly cleansed and packed high up with pledgets soaked in a mixture of equal parts of 20 per cent. cocaine solution and adrenalin, or the tablets of adrenin and novocain will be found very convenient, especially in visiting practice. The packing should be left in for from 15 to 20 minutes. The anterior part of the septum should also be sprayed with a 5 per cent. solution of cocaine a few minutes before the puncture is made. Any long hollow needle of at least 2 millimeters bore will do, but one of the most convenient forms is that introduced by Watson Williams, as it is fitted with a handle as well as nozzle to which an india rubber tube can be attached. The point of the needle is placed high up under the inferior turbinal at about an inch and a half from the labial margin of the nostril. When it has penetrated the sinus, if no flow of pus takes place through it, the tube of a Politzer bag should be attached to the proximal end and air forced through. If pus is present it may bubble into the middle meatus. Some sterile normal saline solution should next be forced through if no pus is found, and this may loosen accumulations of thickened matter. If pus or even a distinct turbidity is observed in the returning fluid, the only question that remains open is whether the suppuration has taken place in the antrum or in the frontal sinus, the antrum serving merely as a passive reservoir. Should these methods fail to demonstrate pus, peroxide of hydrogen either as a ten-volume solution or some of this diluted with equal parts of sterile water may be syringed through, when, if pus is present, effervescence will be observed in the middle meatus. If no pus is expelled by any of these methods and it recurs in the middle meatus, it does not come from the antrum. This method is so simple and on the whole so certain that exploration through the alveolus or through the canine fossa need not be thought of. Possible errors may arise when suppuration occurs in connection with malignant disease, but in these cases the condition of the anterior and nasal walls as well as the age of the patient will help to clear up the diagnosis. It should be remembered that a dental cyst never communicates with the nose and cannot be washed through the maxillary outlet, though its contents may discharge through the exploring needle in the inferior meatus. Having washed out the antrum and found pus, we have now to determine whether it originated there. If we reexamine the nose, and, in spite of the thorough cleansing we have carried out, we find pus in the middle meatus, it can come only from the frontal sinus or anterior ethmoidal cells. If there is no reappearance of pus it is almost certain that only the antrum is suppurating. If pus was found on washing out the antrum, and recurs quickly in the middle meatus, both the frontal sinus and the antrum are probably affected, but this is one of the most difficult points to settle, and an exact diagnosis can sometimes be made only retrospectively after the operation on the antrum. Should polypi be seen in the middle meatus these are more often associated with suppuration in the higher cavities, frontal or ethmoidal. The pus from these also recurs more rapidly in the erect position,

and it may be taken as a general rule that the frontal sinus is not affected without some concurrent suppuration in the anterior ethmoidal cells. The pus from the frontal and ethmoidal cavities is rarely so fetid as that from the antrum. Having excluded the antrum, or decided that it shares with the superior cavities in the suppurative process, the anterior end of the middle turbinal should be removed. This will be required in any case as part of the treatment. The frontal sinus can then be catheterized and washed out. If no pus recurs after this, then only the frontal is affected. If it does appear, it comes from the anterior ethmoidal cells. Owing to the small amount of pus secreted by some of the ethmoidal cells, it tends to dry in yellowish-green crusts on the mucous membrane, interfering with the nutrition and producing erosions or atrophy. In patients so affected the appearance and symptoms closely resemble those seen in atrophic rhinitis with ozena.

Suppuration in the posterior group and in the sphenoidal sinus cause the same general symptoms. Diffuse headache or pain in the vertex is often sphenoidal, while pain felt deeply behind the eyes may be ethmoidal in origin. In all these sinus

Fig. 1—Rectangular chisel for opening the maxillary antrum.

troubles the subjective symptoms are of little help except as presumptive evidence. Pus from the posterior ethmoidal cells or from the sphenoidal sinus appears anteriorly in the olfactory fissure above the middle turbinal. Sometimes cocaine and Killian's long speculum may be used to force the turbinal outward, and so obtain a view of the sphenoidal outlet. The practical point is that, having excluded the cavities of the anterior group, the middle turbinal must be removed as a preliminary to treatment of the remaining group of cells. As regards treatment of the anterior group, no operation other than puncture and lavage should be undertaken in the case of the antrum until this has had a fair trial. When that has failed the cavity should be opened from the nose. The best site is in the inferior meatus, either with or without removal of the middle third of the inferior turbinal. The anterior third is too far forward from the usual site of the deepest part of the cavity and, besides, removal of the anterior third is often followed by inflammation and occlusion of the lacrymal duct. This operation was originally proposed by Mickulicz and has been modified or approved by various operators. I have myself for many years used the rectangular chisels (Fig. 1) and angular perforator (Fig. 2), and their use facilitates the

Fig. 2—Angular trocar for antral wall.

removal of any desired area of the inner wall in a few seconds. In the majority of cases the intranasal operation, followed by lavage, is able to bring about a cure. It is only where the mucous membrane is much thickened and polypous that operation through the canine fossa, with counter opening to the nose, need be thought of. In any case the intranasal operation provides the counter opening should the canine afterwards become necessary. Surgical treatment of chronic suppuration in the frontal sinus and anterior ethmoidal cells should begin by clearing the middle meatus of all obstruction. If this gives no relief the anterior end of the middle turbinal should be removed and the frontal sinus regularly washed out by means of Hartmann's cannula. Should this prove unsuccessful or impracticable, the question of external operation by Killian's, the Ogston-Luc, or other method has to be considered most carefully. The record of the past ten years shows that a very high mortality attends these operations from cerebral or orbital complications or from osteomyelitis. It has always to be considered whether the inconvenience suffered by the patient is worth the risk shown by an admitted mortality of 10 per cent. The anterior ethmoidal cells can be approached intranasally and broken down either by curette under general anesthesia or better at repeated sittings by forceps with cocaine and adrenalin. Where the cells extend far out or backward under the orbit these can be reached only by external operation. As a preliminary to all these operations, skiagraphs, which are latterly so much clearer than they used to be, will be found most useful in determining the position and limits of the various cavities. Sometimes the suppuration in the nose may be due to multiple sinusitis. The methods of diagnosis here are the same. As regards treatment, it should be remembered that here it may be very prolonged and that the prognosis is more doubtful than where only individual cavities have to be dealt with. If the palliative treatment, by puncture and lavage, removal of the middle turbinal, and regular attention on the part of the patient, fails to bring about a cure or an entirely tolerable condition, the question of radical operation again arises. Should more extensive operation be decided on, it is best, in case of multiple sinusitis, to deal first with the ethmoid and clear all the attainable cells thoroughly in the manner indicated. If the frontal sinus still suppurates and the patient decides to have the operation, it should next be opened, and, if pus has been found in the maxillary antrum, the intranasal drainage of that cavity should be established on the same occasion. If the sphenoidal sinus participates in the multiple inflammation, it should be opened in connection with the treatment of the ethmoidal, leaving always the frontal and maxillary cavities to be dealt with last.

TRICUSPID REGURGITATION, AND STERN'S POSTURE AS AN AID IN ITS DIAGNOSIS.

By LOUIS BERTRAM SACHS, M.D.,

NEW YORK.

There is no doubt that organic disease of the tricuspid valve is of relatively rare occurrence. But it is the opinion of many clinical observers that a structural change in this valve is more common than statistics show. Relative tricuspid incompetency is a comparatively frequent fact, since it occurs at some time in the course of a dilating right heart as a consequence of left-sided disease of the heart. Notwithstanding the frequent occurrence of this relatively common cardiac affection, it has been the wont of the general practitioner completely to ignore dextrocardiac murmurs and solely di-

rect his attention solely to the left side of the heart. This lack of knowledge of the dextrocardiac murmurs among the general practitioners can be attributed to the very slight attention which textbooks and clinical teachers pay to this important subject. The murmur of tricuspid insufficiency, when unaccompanied by any extensive dilatation of the right ventricle and when auscultated in the ordinary erect or recumbent posture, is very evanescent, and so has frequently escaped the attention of even very careful and experienced clinicians.

When accompanied by or due to advanced disease of the left side of the heart, the symptoms and physical signs of this condition are so evident and pronounced that it ought to be easily recognized by the average practitioner. The comparatively very common occurrence of the murmur of tricuspid regurgitation has led Mackenzie to the belief that normally the valves are barely able to close perfectly the tricuspid orifice. This same authority states that the absence of a murmur is no evidence that tricuspid regurgitation does not exist, for it is a frequent occurrence to find evidence of tricuspid incompetency in the character of the jugular and liver pulsations and the greatly widened orifice found post mortem, while during life there was no systolic tricuspid murmur. The absence in these cases of a murmur may be due to a weakened wall and a wide orifice.

Tricuspid regurgitation gives rise to a murmur which is soft and blowing in character, taking the place partially or entirely of the first tricuspid sound. The slighter forms of tricuspid murmurs are limited to a small area over the middle of the sternum, and may exist with little, if any, appreciable increase in the size of the heart. When there does exist an increase in the size of the heart the murmur may be heard over the whole of the anterior cardiac area. The point of maximum intensity is to the left of the sternum, although it may occasionally be heard to the right of the sternum. In cases of marked tricuspid regurgitation, the symptomatology and physical signs are very distinctive. The chief symptom is dyspnea, which ranges in intensity from breathlessness on exertion to orthopnea, even when the patient is at rest. Indigestion is present, distention of the abdomen is of frequent occurrence, and edema of the legs sets in early in the disease. Marked cyanosis is present, and the visible veins in the temples, neck, and arms are dilated and prominent.

The regurgitation of the blood from the right ventricle into the larger veins of the body results in the production of the venous pulse. This venous pulse, which is most distinctly observed in the jugular veins, differs from the pulse of simple engorgement by being more intense and by its rhythm, which is presystolic-systolic in time instead of diastolic-presystolic. Mackenzie has shown that in the tracing of a venous pulse due to tricuspid insufficiency the auricular wave disappears and the ventricular wave increases in size and occurs earlier in relation to the ventricular output than in normal cases. This is called the ventricular form of venous pulse. The venous-hepatic pulse is a characteristic phenomenon of tricuspid insufficiency. It occasionally appears earlier than the jugular venous pulse. This form of venous pulse corresponds to a presystolic-systolic dilatation of the hepatic-vascular net. The apex beat of the heart is diffuse and may extend into the fext axilla. Percussion shows that the transverse dulness is increased, extending more to the right than normal. Schwartz states that if this dulness is more than three fingers' breadth to the right of the sternum, it should be recognized as being due to relative insufficiency rather than to organic disease of the right ventricle or tricuspid valve.

From the above clinical symptoms and signs it is very evident that there should be no difficulty in the diagnosis of a marked tricuspid regurgitation It is in the slighter forms of the disease that systolic-tricuspid murmurs are overlooked.

In a paper published in the *Archives of Diagnosis* for January, 1910, Heinrich Stern calls attention to a new posture in the recognition of tricuspid regurgitation. With the aid of this posture it is possible to induce the characteristic murmur of tricuspid insufficiency when it has been absent, and to make it more distinct when it is vague and indistinct. When a patient is in the recumbent posture, if the head be lowered, the jugular veins become distended, and as a rule begin to pulsate. If the head be lowered beyond a certain degree the pulsation and engorgement recede. Lowering of the head in this manner produces a stretching of the muscles of the head and a stretching of the jugular veins. The stretching produced by the lowering of the head is reflected in the tricuspid area, and murmurs are now evident which were not heard before, or which were quite indistinct. It will also be noticed that the apex beat is now also more pronounced, and that any other accompanying murmurs are now more audible than when the patient was in the ordinary recumbent position. Tricuspid murmurs are audible on some days, inaudible on others. In Stern's posture a tricuspid murmur once audible is always audible. The venous-hepatic pulse, as before stated, is a characteristic phenomenon of tricuspid insufficiency, and in Stern's posture this phenomenon can very frequently be observed. Stern noted that the pulsations were more marked over the left lobe of the liver and in the epigastric region, and though they are apt to disappear suddenly they frequently return when the patient is in Stern's posture.

The following two case histories will show the great aid afforded me by Stern's posture in the recognition of tricuspid regurgitation:

Case I.—Mr. B., a banker, 53 years old, had never performed any hard physical labor and had had only slight mental strain, which was due to the responsibility of the education of his motherless children. I saw him in November, 1908. He had then been ill for about four months. He had been in a Western sanatorium, where he was treated without any benefit to himself, no positive diagnosis having been made. His previous history was negative. Present history: During the past two months, the patient had violent attacks of dyspnea, which finally developed into orthopnea. He was more or less cyanosed, nearly all the time. When the patient was placed in Stern's position a distinct ventricular form of venous pulse in the neck and temples and an hepatic venous pulse were present. Examination of the heart in this position elicited a slight dilatation of the entire heart, especially of the right side. Upon auscultation of the right heart in Stern's posture a soft blowing murmur over the middle of the sternum was heard, synchronous in time with the first sound of the heart. Auscultation of the left heart in Stern's posture revealed a marked accentuation of the apex beat, but no distinct murmurs could be heard. Upon

examination of the heart in the erect and recumbent positions at this time, there was no evidence, beyond a slight dilatation of the heart, of any valvular disease. Examination of the urine showed no signs of renal involvement. The liver was slightly enlarged, but all the other organs of the body were apparently not grossly affected. About two months after the first examination, the patient had all the symptoms and physical signs in a highly prominent degree. He succumbed soon after.

The prominent features of this case were: The presence of the characteristic signs of tricuspid regurgitation, *i.e.* great dyspnea, developing into orthopnea, and in Stern's posture a ventricular form of jugular venous pulse, an hepatic venous pulse, and the presence on examination of the right side of the heart of the soft blowing murmur over the middle of the sternum, systolic in time. The fact that the murmur was inaudible in any of the positions for the examination of the heart excepting Stern's is evidence enough of the great value of this posture in auscultation of the heart.

There can be no doubt that the primary illness was due to a tricuspid regurgitation, for a careful examination of the left side of the heart did not show a single lesion which could in any way account for the symptoms present.

Case II.—Mr. R., 58 years old, first seen by me on June 13, 1909. Had been rejected nine years previously by a life insurance company on account of the presence of albumin in the urine. The patient had been treated for mitral disease, but there was absolutely no evidence of any disease of this valve. Present condition: Patient complains of constant dyspnea, pressure in the abdomen, indigestion, headaches, and vertigo. The physical examination revealed the presence of ascites, of edema of the lower extremities, of slight enlargement of the liver, but no pulsation in the recumbent or erect postures, the spleen was not palpable, the lungs were slightly emphysematous, and the urine showed all the evidences of a chronic parenchymatous nephritis. Examination of the heart showed a distinct dilatation of the right side, and a slight increase in size of the left. The apex impulse was slightly outside of the left nipple. No arrhythmia was present. In the erect posture, the apex impulse was weaker than in the recumbent position. In Stern's position the apex beat was not accentuated. In this position examination of the right heart revealed the presence of a distinct murmur in place of the tricuspid first. No murmur of this valve could be elicited in the erect or recumbent postures. Examination of the aortic valve in the recumbent position showed both sounds to be but faintly audible. In Stern's posture, there was a probable accentuation of the second sound, as the first was not audible. In this position the ventricular form of venous pulse was present, while it was absent in the recumbent or erect postures. No murmur of the mitral valve could be heard. Under heart tonics and diuretics the patient improved to some degree, but he eventually died with all the symptoms and signs of cardiac dilatation.

In this case one of the most prominent symptoms was the presence of great dyspnea, which is a sign of cardiac asthma, thus pointing to disease of the right chamber of the heart. The ventricular form of venous pulse was present and the characteristic murmur was audible in Stern's position, while it could not be elicted in the erect or recumbent postures.

526 West One Hundred and Eleventh Street.

ABSTRACT OF TREATMENT OF ARTHRITIS DEFORMANS IN MONTEFIORE HOME.

WITH REPORTS OF CASES.*

By SAMUEL W. BOORSTEIN, M.D.,

NEW YORK.

For many years cases of arthritis deformans were considered incurable and after trying various methods, the general practitioner would say: "I can do absolutely nothing for the patient, send him to an institution." As a result of this, an institution like ours received many of these cases with the understanding that they were to remain there for the rest of their days. They were put in the wards and remained there till they died from some intercurrent disease.

Lately a great deal of work has been done in England on arthritis deformans and good results have been reported, but emphasis is put on "systematic treatment." The physician and the patient must have great patience in order that good results may follow.

About eight months ago, under the service of Dr. George R. Elliott, we started careful "systematic treatment" on our arthritis cases and the results have been so encouraging as to justify persistence in this line of treatment. We administered this treatment to ten patients only of a group of twenty-five. Three of the patients treated are walking and three others have improved so much that they will probably be able to walk in a short time. We have been able to relieve the distressing symptoms of the other patients.

The treatment is divided into (1) that of the general condition and (2) that of the joints. General treatment: Since infection plays an important part in bringing on the disease and aggravating the condition, we look first for the source of the infection and examine the mouth for carious teeth, pyorrhea alveolaris, and diseased tonsils and remove the source of infection when found. The digestive tract is very carefully attended to, since gastrointestinal disturbances aggravate the symptoms, and whenever patients are constipated they complain of marked pain and discomfort in the joints. The urine is examined two or three times a week and when indican is found in large quantities a high enema is given. As a routine measure each patient receives two or three enemata a week, as a result of which the pain in the joints is greatly relieved. Diet: We allowed the patients to eat whatever agreed with them and tried to have them gain weight in order to increase the nutrition of the joints and so improve the atrophied muscles. We did not try to diminish the uric acid unless the patient showed gouty tendencies. We made metabolic studies of the digestion in some cases; the nitrogen intake and output were carefully estimated and we found no change in the symptoms when a large amount of nitrogen was given. The results depended only on the form in which the nitrogen was administered. We studied each patient individually and gave him the diet that agreed with him. Milk, cheese, and buttermilk were given in large quantities since it is claimed that calcium has a markedly beneficial influence. The digestion was improved by this diet, but it had to be changed on account of the monotony. Lately we have

*Read before Section on Medicine of the New York Academy of Medicine, November 21, 1911.

started to use the calcimeter and where we have found a deficiency in calcium we have given food rich in this element. Hygiene: The patients were kept out of doors as much as possible, being wheeled out on the balcony even when the weather is cold, provided, however, that it is dry.

Hydrotherapy: Bathing is very useful. It increases the elimination of toxins. Three times a week we place the patients in steam boxes in a sitting posture for ten minutes at a temperature of 200 to 225°. The head is covered with a towel moistened in ice-water. This hot-air bath is followed by a spinal douche at a temperature of 90° and a pressure of 20 pounds, which increases the tone of the muscles in the back. Dry heat: Baking is found to be very beneficial. It produces an immediate and powerful stimulation of the vital functions and brings an increase of blood to the parts, and if this procedure is followed by massage the effect is doubled. We use the Turnauer hot-air apparatus, in which the limb is kept for 45 minutes at a temperature of 250 to 300°. The pain is markedly relieved by the baking and the increased amount of blood in the affected parts permits a more efficient massage. Light baths have lately been used in metabolic disturbances, the benefit being attributed to the promotion of the extensive elimination of the products of poor metabolism. Since most of our patients are bedridden we have constructed a special recumbent light bath. Active and passive hyperemia is very useful. We are using Bier's method of passive hyperemia—in the beginning for two or three hours daily and later for six or eight hours daily. Still later bandages are left on over-night. This method is very effective in stopping pain. We have used it before employing massage and have found that the patient had less pain during the process. Electricity: The faradic or galvanic current has very little effect. The static current is claimed by some to do good. We have applied the "wave current" to the joint for fifteen or twenty minutes, or the spark for five minutes. They seem to influence the pain favorably and have a good tonic effect. Probably some good is derived from the vibratory movements.

Massage: This, together with exercises, is the most useful part of the treatment and constitutes an important part of our program. Patients usually object to it in the beginning, but if one gains their confidence they will bear it. The massage is given only three times a week and not too vigorously. We have been accustomed to give massage after some hyperemic measure, such as baking, or the application of hot water, of Bier's hyperemia, steam boxes, or light boxes. Patients complain of less pain if the massage is given in this way. The massage increases the nutrition of the joints and diminishes the possibility of ankylosis, muscular atrophy, and contractures. The patients have done a certain amount of massaging themselves. Exercises: These have been found to be the most effective part of the treatment, but also the hardest to accomplish, since the patients are not very willing to perform them. A pulley-weight exereiser helped a great deal in cases in which the patients did the exercises themselves. The patients were compelled to roll the wheel chairs themselves and to do exercises with their hips with the aid of a pulley attached to the ceiling. They had to rock on a rocking-chair for several hours daily. For their fingers we used rubber balls which patients had to press hard. We made them walk as early as possible.

We paid great attention to prevention of new deformities and this was done by the exercises and by keeping some parts in splints for part of the day. We use plaster splints for the night since the voluntary control of the muscles is lost and contractures may increase.

Treatment of deformity when present: We have used gradual straightening of the limbs and putting them in plaster for a day or two. Recently we have not broken up joints under anesthesia. We have seemed to get better results by straightening them gradually in several sessions. For straightening the fingers we made wooden splints well padded and applied direct pressure over the joint. Operative treatment is advised by some clinicians, but we have had no occasion to use it. Medicinal treatment: After using most of the drugs recommended we have ceased using any of them, excepting occasionally, when we give aspirin or tincture of gelsemium to stop the pain. The mechanical treatment has succeeded in stopping the pain. For local applications we use ichthyol or chloral hydrate ointments.

Résumé of Routine Treatment.—Each patient as soon as he enters the orthopedic department has his casts, *x*-ray, and photograph taken and a careful description is made of the joints on the "question blank" so that a good record of the changes can be kept. Then the patients are given the following treatment: Baking followed by massage three times a week; "steam boxes" on the intervening days; light baths twice a week; Bier's hyperemia every day for six or twelve hours; enemata twice a week; exercises daily, and static electricity three times a week. Casts are taken every three to four months. For carrying out this treatment we have given nurses special training and have elicited their personal interest in this special kind of work.

The following is the outline of a case: M. H., age twenty-seven, teacher. Entered the Home in February. Bedridden for about two years. Knees swollen and contracted to an angle of 45 degrees. Marked pain in all the joints; unable to dress, undress, and feed himself. Received treatment for eight months. He now walks, although with a brace, and has no pain whatever. Dresses, undresses, and shaves himself, and writes well without any discomfort.

PLAN OF "QUESTION BLANK."

Name: Age: S. M. W. Date:

Arthritis Deformans.

1. Occupation: knitting, sewing, washing.
2. Atmospheric influences: exposure to cold and wet.
3. Financial condition:
4. Hygienic surroundings:
5. Hygienic surroundings:
5. Sex:
6. Age at onset:
7. Family history: rheumatism, gout, or any joint disease:
8. Predisposing causes: worry, anxiety, mental strain, etc.
9. History of preceding infections: intestinal, purulent, etc.
10. Associated diseases: tuberculosis, heart disease, Raynaud's disease, scleroderma.
11. Exciting causes: cold, dampness, reflex irritation, *e.g.* uterine.
12. Subjective findings: pain, history of redness, history of swelling, digestive system.
13. Objective findings: pulse; temperature; blood count and Wassermann reaction; Gastric Analysis; urine; examination of feces; examination of

heart; bloodvessels and blood pressure; lymphatic glands; nails; mouth, including teeth, gums, tongue, and tonsils; nasal examination; ear examination; emotion and temperament; fibrous nodules; tendon reflexes; muscular system, especially atrophy; joints first involved; ankylosis (fibrous or bony); condition of skin over joints (pigmented or not), (glossy or not); spine; x-ray findings; joint involved, description, etc.

THE SIGNIFICANCE OF THE SPLASHING SOUND IN THE GASTROINTESTINAL CANAL.

By MARK L. KNAPP, M.D., LL.B., LL.M.,

NEW YORK.

In the physical examination of the abdomen in gastrointestinal diseases we make use of what is known as the splashing sound. This is a sound which is produced by the simultaneous presence in a hollow viscus of gas and liquid. The sound is elicited by sharply striking the abdomen with the tips of our fingers. It is also elicited by shaking the body back and forth or laterally. This physical sign has been made use of especially in connection with the stomach. Whenever the splashing sound is found in the region of the stomach it has been interpreted, first, to mark the boundaries of the stomach, and, second, to give us information as to the condition of the propulsive power, of the tonicity, of the stomach. We are taught that, once we find the splashing sound we must try for it as low down as we can get it and there, at the lowest point, mark off the lowest level as being the greater curvature of the stomach. There should not be any exception to this teaching, provided we are sure that the splashing sound is engendered in the gastric cavity, which latter must be proven as a fact and not be merely assumed. The history of the case I am about to narrate shows that, notwithstanding the presence of the splashing sound in the region of the stomach, the stomach was absolutely innocent; that the sound elicited in the region of the stomach did not originate in the stomach. Concerning the second proposition, we are told that the presence of the splashing sound in the stomach indicates atony of the stomach; this I deny unqualifiedly and I shall later prove the correctness of my contention.

In this contribution I wish to give the history of a case in which there was the splashing sound; but the splashing sound came not from the stomach, it came from the bowel.

Mrs. R. P., forty-two years, native of the United States, gave the following history on May 10, 1911: Sick for some time; pain in the left side which is often of such severity that she crawls on the floor; feels tired when getting up in the morning; feels very miserable after meals; belching after meals; at times there is a burning sensation in the stomach and a bitter taste in the mouth; she feels always dry and thirsty; has flashes of heat and cold and a sensation of weight and heaviness behind the sternum; she has very weak spells; suffers from constipation; has pain in the heart on walking; takes a long time to fall asleep, but then sleeps soundly; has left temporal and, quite occasionally, also occipital headache; there is frequent micturition of small quantities.

On physical examination I found a splashing sound in the left side in the region of the splenic angle of the transverse colon. The aspiration of the stomach brought forth no gastric contents. The test meal examination yielded only some 10 c.c. of chyme, which reacted to free hydrochloric acid (by tropaeolin 00), and the microscope showed budding, sporulating yeast cells. My diagnosis was incipient insufficiency of the pylorus and zymosia gastrica. Under treatment she began soon to feel well, and left the city for the summer. She remained well until she committed voluntary errors in her diet and again visited me on October 16, 1911. She came fasting, and again complained of pain in the left side, but this time she suffered no headaches; she blamed her diet for her present suffering. I again examined her abdomen and again found the splashing sound, which did not reach any lower than the greater curvature of the stomach, but it did spread laterally quite a distance to the right of the median line. I aspirated the stomach, but could not get any contents. I then introduced the usual quantity of fluid for the purpose of lavage, but the syphoning brought up more than I introduced into the stomach. Another examination of the abdomen after the lavage for the purpose of getting the splashing sound proved negative; no more splashing sound after the lavage.

What does this history teach? The facts are that we had here a splashing sound, that the splashing sound was limited to the area of the stomach as far as the greater curvature was concerned, and that the aspiration of the stomach proved that the stomach was empty and that therefore the splashing sound could not possibly have come from the stomach. Therefore, had I relied upon the splashing sound as indicating the limits and boundaries of the stomach, I would have had to assume the presence of a gastrectasy of the horizontal type. The events proved that such an assumption would have been highly erroneous.

Besides this, were I to follow the books, which, concerning atony of the stomach, have followed and copied the erroneous teachings of over two thousand years, I would have had to assume also here the existence of atony of the stomach, since the books teach that the splashing sound indicates atony. Now as to the diagnosis of atony. Atony of the stomach or of the intestines does not exist, all other teachings to the contrary notwithstanding. True, I have myself reported a case of "atony of the duodenum" (*New York Medical Journal*, May 23, 1903) and have always taken great pride in the diagnosis, which was corroborated by operation at the Presbyterian Hospital. But I have since changed my views, not as to the facts narrated in the article just mentioned, but as to the interpretation of the condition which we are taught to call atony. The calling of the stomach or any part of the intestine "atonic" is adding insult to injury, it is a gratuitous affront to the integrity of the muscular coat of the organ or part of the organ which is under consideration. Relating to the misleading term "atony of the stomach" I wrote, *in extenso*, in my first article on insufficiency of the pylorus (*Philadelphia Medical Journal*, May 24, 1902) and since then I have applied the same reasoning to intestinal conditions as well. The presence of liquids and gases simultaneously in a given area simply means that these liquids and gases are, at least for the time being, confined in such area and, for the time being, such confinement indicates an obstruction at both outlets of the viscus in which the liquids and gases are confined. This

obstruction may be quite temporary, such as an ordinary more or less spastic contraction, or it may be of a permanent nature. This latter condition obtains when there is an organic obstruction existing either within the organ or without it. So that the obstruction may be benign or of a malignant nature. Where the obstruction is produced by a spastic contraction merely, we are dealing with a benign condition and, with reference to the stomach, I have termed such obstruction "stenosis pylori ab irritatione." But where the obstruction is produced by a neoplasm within the lumen or by a cicatricial contraction following a previous ulcer, or where the obstruction is produced from without by a neighboring organ pressing against it, or by a kinking of the gut or by an adhesive band keeping two arms of a piece of intestine kinked and permanently matted together, we are dealing with a permanent obstruction. In any of these given conditions, it is highly illogical to blame the stomach or the piece of the bowel within which the fluid is contained, for lack of propulsive power and call the respective organ atonic. Pertaining to the stomach the physical appearance of the aspirated chyme in such "atonic" conditions not only proves that there was no atony, but that the very contrary condition is the fact, namely, that those presumed cases of atony in reality show "hyper-tony." If the doors are locked, how can the contents escape? If there is a stenotic condition of the pylorus, how can the chyme pass into the duodenum? Is it due to laziness on the part of the muscular coat of the stomach, is it due to atony of the stomach? No, the contents of the stomach cannot get away, not because the musculature of the stomach is atonic, but because there is a locked door, there is a stenosis of the pylorus. The same reasoning applies to the intestine. The splashing sound is produced under these circumstances not because there is an atonic condition of either the stomach or some part of the intestine, but because there is some temporary or permanent obstruction present which keeps the fluids and gases confined within the respective limits for the time being. The splashing sound proves only an evanescent or temporary obstruction, but never atony.

The second lesson this case teaches is that we must not assume that the splashing sound, although elicited from the area where the stomach is situated, comes from the stomach. This case teaches that the splashing sound in the region of the stomach may come from the jejunum. Had I here relied upon the splashing sound as indicating the boundary of the stomach I would have had to assume the existence of a gastrectasy of a horizontal type inasmuch as the splashing sound extended quite some distance to the right of the median line. I have been taught that such gastrectasies exist, but I assume no responsibility as to the correctness of such teaching. Indeed, I am inclined to doubt very much the existence of such a gastrectasy. In the light of my investigations dating back to 1902 and the now demonstrated fact of the existence of insufficientia pylori, it is easily possible that what has been assumed to be a horizontal gastrectasy in reality was an absolutely relaxed pylorus. Added to this condition an obstruction of the duodenum, which so often occurs at the site where it passes through the two prongs of the fork formed by the abdominal aorta with the superior mesenteric artery, we have a condition created which gave the mistaken picture of a gastrectasy of a horizontal type. When the stomach was inflated the inflated air passed beyond the stomach into the duodenum since there was no contracted pylorus to retain the air in the stomach and the inflation distended both the stomach and the duodenum. As insufficientia pylori at that time was unknown, the duodenal inflation shown by the distention reaching to the right of the median line was interpreted wrongly. The entire distended area was assumed to show the confines of the stomach while it might have been the distention of the stomach and of the duodenum. Viewed in this light, insufficientia pylori not being known, we can easily understand why a condition was called horizontal gastrectasy if the inflation caused bulging beyond the medial line.

The splashing sound is an interesting phenomenon, but it must not be used either to localize the stomach or to define its boundary, and most assuredly it does not prove any atony.

616 Madison Avenue.

The Halsted Operation in the Treatment of Mammary Cancer.—E. Tournier advocates the use of the Halsted operation for the extensive removal of the structures in the axilla and the pectoral muscles, on account of the lessened likelihood of recurrence. The objections that have been made to this operation are that it is unnecessarily mutilating and causes disability of the corresponding arm and shoulder. The author thinks that this disability is more due to adhesions which form from immobilization of the arm during healing; and injuries to the posterior circumflex nerve while cleaning out the axilla in the dark. If the arm is allowed to be moved after operation and the nerve is looked for during the open operation this disability will be avoided. That these muscles are not necessary to the movements of the arm is shown by the perfect results obtained after their removal and when they are congenitally absent. The fact that recurrences are rare in these muscles and that the lymphatics of the breast do not reach these muscles is not to be considered in this matter, since there are authentic cases in which recurrences have occurred between the pectorals in a few glands located there or in the interstitial connective tissues of the muscles.—*Gazette de Gynécologie.*

Senile Pleurisy.—Oppenheim and Crepin state that among 2,000 old people they have observed 41 pleural effusions, 29 of which have been diagnosed during life, and 12 have been revealed by the post-mortem examination. Among the last 4 had died suddenly, without any premonitory sign or symptom. The average age of the cases considered was 70, and the condition was about three times more frequent in men than in women. Both sides seemed to be equally often affected. In the vast majority of cases the general condition was very poor. After a study of several typical cases the authors allude to the extreme severity of the disease and to the great frequency of sudden death. The death rate was 65 per cent. The only rational treatment of senile pleurisy with effusion, according to the authors, is paracentesis, which must be performed as soon as the diagnosis is made.—*Progrès Médical.*

Paralysis of the Right Third Nerve Following Ethmoidal Operation.—H. J. M. Wright reports the case of a man, aged thirty-six, who was first seen in April, 1911, with a history of nasal polypi for about eight years. Following an intranasal ethmoidal operation on the right side he developed an orbital hematoma and complete right third nerve paralysis. The pupil is now, six weeks after the operation, smaller and reacting, and the ptosis is less, but the condition is otherwise unaltered. Vision of the right eye is unaffected.—*Proceedings of the Royal Society of Medicine.*

New York, February 10, 1912.

A NEW THEORY OF THE MECHANISM OF SENSATION.

THE late Hughlings Jackson laid the foundation of all modern studies of cortical function by his observation of focal irritations of the motor zone, in cases which are now included under the name of Jacksonian epilepsy. The localization of sensory functions in the cerebrum has not been so definitely determined, although these functions have been supposed to reside in regions of the cortex nearly identical with those that are concerned with motor activities. But apparently a great step has just been taken in the interpretation of the mechanism that underlies the elaboration of sensory phenomena. In their third contribution on the sensory disturbances that result from cerebral lesions Henry Head and Gordon Holmes present in the *Lancet*, January 20, 1912, an ingenious theory of the mechanism of sensation. This theory is based upon the study of lesions situated in different parts of the brain, but more particularly upon the study of twenty-four cases in which a lesion of the optic thalamus was present. In these cases, in addition to the loss of sensation resulting from the interruption of the afferent paths to the cortex, there was added a phenomenon which was the result of the destruction of certain parts of the optic thalamus. This phenomenon was the tendency to react excessively to certain stimuli, whether painful or pleasurable. There was "an actual overloading of sensation with feeling tone." The prick of a pin, although less sharp and less distinct on the abnormal side of the body when compared to the normal side, nevertheless was decidedly more distressing and painful. The difference was one that concerned the affective phase of consciousness, the phenomenon of well-being or comfort as contradistinguished from that of pure sensation. It is this psychological principle which now finds an anatomical basis in the theory proposed by Head and Holmes, who place the seat of this affective faculty in the optic thalamus. This organ responds to all stimuli capable of evoking pleasure or pain, or consciousness of a change of state, and is the seat of the feeling tone associated with visceral sensations.

The optic thalamus plays a triple rôle with regard to sensory impulses. It contains the termination of all sensory paths, which are regrouped and distributed either to the cerebral cortex or to the essential gray matter of the thalamus. This essential gray matter is the center for the fundamental element of sensation, namely, the feeling tone, which resides exclusively in the optic thalamus. The lateral part of the optic thalamus contains the organ through which the cortex influences the essential thalamic activity, by controlling and checking it. If this region is injured the inhibitory influence of the cortex is removed, with the result that the thalamust reacts without restraint to all stimuli capable of arousing affective states.

All afferent impulses on their way to the cortex are regrouped at the thalamic junction and act upon two terminal centers. One is the essential organ of the thalamus, which, as we have seen, is concerned with the appreciation of pleasure and discomfort. From the other center the afferent impulses are transmitted by way of the internal capsule to the cerebral cortex. Thalamic and capsular lesions, with the consequent loss of sensation, show that there are five main groups of these impulses: (1) those underlying postural recognition and the appreciation of passive movement; (2) those underlying the appreciation of tactile differences; (3) those concerned with spacial discrimination; (4) those concerned with localization, and (5) those impulses underlying the appreciation of thermal differences. When these impulses reach the cerebral cortex the resulting sensory changes are brought into relation with one another simultaneously, and with experiences that have gone before. The center also has the power of focusing attention upon these sensory changes. But, to quote Head and Holmes, "in addition to its function as an organ of local attention the sensory cortex is also the storehouse of past impressions. These may rise into consciousness as images, but more often, as in the case of special impressions, remain outside central consciousness. Here they form organized models of ourselves which may be termed 'schemata.' Such schemata modify the impression produced by incoming sensory impulses in such a way that the final sensations of position, and of locality, rise into consciousness charged with a relation to something that has happened before. Destruction of such 'schemata' by a lesion of the cortex renders impossible all recognition of posture or of the locality of a stimulated spot in the affected part of the body."

All stimuli in daily life that pass to the cortex excite both the thalamic and the cortical centers, but one more than the other. Thus the stimuli that result in the recognition of posture arouse almost exclusively the discriminative sensory mechanism of the cortex, while visceral sensations may be entirely restricted to the activity of the thalamic center. All thermal stimuli arouse both the cortical and the thalamic centers; the sensations of warmth and of cold in addition to the purely thermal recognition contain a prominent affective element, one of comfort or discomfort, of pleasure or pain.

But the thalamic center is not an independent one. It is dominated by that of the cortex, just as the latter inhibits the motor or tonic impulses that emanate from lower levels of the cerebrospinal

axis. Loss of the cortical control, in the case of these impulses that have both a sensory and an affective content, results in a heightening of the affective tone, as has been amply demonstrated in the cases of thalamic disease presenting the "thalamic syndrome."

This theory, which is based upon ample clinical and pathological data, fills a wide gap in the present knowledge of the physiology of the brain. By assigning an organic substratum to the "affective" phase of consciousness, which has long been recognized by psychologists, it also helps to bridge the chasm between the physical and the psychical.

BRILL'S DISEASE AND TYPHUS FEVER.

Those familiar with both diseases have for some time suspected that the symptom-complex so clearly described by Dr. Nathan E. Brill, which has become generally known as Brill's disease, was a mild form of typhus fever. From Brill's reports it is apparent that he has recognized the similarity of the two diseases, for he says, "in the case of an epidemic of typhus, in my opinion, it would be simply impossible to say that those cases which I have described were not mild typhus fever." Nevertheless he refuses to admit the identity of the two diseases. Friedman, who had observed cases of typhus fever in Russia, laid special emphasis upon their similarity in a paper read before the New York Academy of Medicine in May, 1911. (Medical Record, September 16, 1911, p. 606). Louria of Brooklyn, in an article in the Medical Record of August 26, 1911, also notes the striking similarity of the two diseases, and quotes Goodall of London, who regards the two diseases as one and the same.

The recent findings of Anderson and Goldberger,* which seem to show that the two diseases are identical, will, therefore, cause little surprise. These workers in experimenting with monkeys found that an attack of Brill's disease which they were able to produce in these animals by inoculation rendered the monkeys immune to the strain of typhus fever now prevailing in Mexico, and that the reverse was also true, namely, that an attack of Mexican typhus fever produced in monkeys an immunity to Brill's disease. This seems to indicate that the typhus fever which has been prevailing in the plateau regions of Mexico and locally is called "tabardillo" is identical with the disease described by Brill. While the presumption is strong, it remains yet to be proven that the typhus fever of Mexico is the same as the typhus of Europe and Asia. This added information concerning a disease which had come to be recognized as a definite entity, but of which the etiology and relationship to other diseases were in doubt, has aroused much interest in New York City, where most, if not all, of the cases of Brill's disease have been reported. The disease is known to have been recognized, however, in other large cities and very possibly greater numbers of cases will be encountered in the future and the occurrence of typhus fever in many large cities may be found to be not uncommon.

*Anderson, John F., and Goldberger, Joseph, The Relation of So-Called Brill's Disease to Typhus Fever, Public Health Reports, Public Health and Marine Hospital Service, February 2, 1912.

Russian physicians recognize a mild form of typhus in that country and say the type of the disease is so modified that the mortality is very low and instances of evident contagion are rare. Goodall asserts that a mild type of the disease is encountered among the Russian Jews in London, and many physicians practising among the same class of the community in this city believe that modified typhus fever exists here also. It would be strange if it did not, and the experiments of Anderson and Goldberger seem to show quite conclusively that it does.

CULTIVATION OF SPIROCHETES.

Spiral microorganisms have been the object of careful study from the time when Schaudinn and Hoffmann described the occurrence in syphilitic lesions of *Treponema pallidum* and suggested that it might be the long-sought-for excitant of the disease. They and their immediate successors, however, could not absolutely prove the rôle of this organism in causing syphilis, artificial cultures being unsuccessful and thus Koch's classic cycle of proof not being complete. Mühlens later succeeded in obtaining fairly pure cultures of spirochetes, but apparently had only partial success in showing that his cultures were pathogenic for animals. In this country Noguchi has done a great deal of careful work in the study of the diagnosis of syphilis by means of the Wassermann and modified Wassermann reactions, and has recently announced the final step in the proof of the relation between *Treponema pallidum* and syphilis (*Journal of Experimental Medicine*, No. 1, Vol. xv), namely, artificial cultivation of the organism and the production of syphilitic lesions in animals by means of the cultures thus obtained.

Noguchi's technique is rather complicated, for he had to use solid media inoculated with a mixture of various bacteria and spirochetes. He succeeded in isolating the *Treponema pallidum* by making subcultures from the periphery of growths where the spirochetes were fairly free from other organisms. In addition, Noguchi found that pieces of sterile tissue had to be added to the nutrient media used before the spirochetes could be grown. His technique, however, is of less interest to the general medical reader than is the fact that the cultures he obtained proved pathogenic for two species of the lower monkeys. To clinch the result, Noguchi was able to obtain a positive Wassermann reaction in the blood of the monkeys successfully inoculated.

About the same time Noguchi studied the common spirochetes normally found in the human mouth and has succeeded in obtaining cultures of two varieties, for which he now proposes the names *Treponema microdentium* and *Treponema macrodentium*. These cultures proved of great interest in throwing light upon the biology of the spirochetes, their modes of multiplication, involution forms, etc. It may be that Noguchi's work will result in the preparation of a luetic antigen for use in the Wassermann reaction superior to the extracts of syphilitic or normal organs now used, and thus change this valuable test into a strictly specific reaction comparable to the Widal test in typhoid fever.

SUBDURAL INJECTIONS OF LEUCOCYTES IN EXPERIMENTAL TUBERCULOUS MENINGITIS.

The importance of leucocytes, especially of the polymorphonuclear type, in the defense of the body against the spread of infection has been recognized for a number of years, Metchnikoff's pioneer work on phagocytosis having been the origin of this explanation of immunity. About two years ago Hiss and Zinsser showed that such defensive action of the leucocytes may apparently be increased by providing the body with extracts of dead leucocytes obtained from animals by injections of aleuronat (*Journal of Medical Research*, XXII, 1910). Their extracts were tried out clinically and seemed to have met with partial success in the treatment of pneumonia, erysipelas, etc. Previous to their work Opie published painstaking studies of the effects of whole leucocytes, as opposed to extracts, in experimental tuberculous pleurisies of dogs (*Journal of Experimental Medicine*, X, 1908). In a recent number of the latter publication (No. 1, Vol. XV, 1912) Dr. Wilfred H. Manwaring communicates the results of similar work in experimental tuberculous meningitis. He produced this lesion by injecting various strains of tubercle bacilli through a trephine opening in the skulls of dogs. Paralysis and death followed in control animals thus infected and not further treated. On the other hand, several other dogs were treated by injections of canine leucocytes, following the inoculation with tubercle bacilli, the leucocytes being obtained by injecting turpentine into the pleural cavity and making suspensions of the cells in the resulting effusion. These animals showed uniform delay in the development of paralysis and life in them was much prolonged. In a few dogs inoculated with small doses of bacilli of low virulence paralysis had been prevented up to the time of publication of Dr. Manwaring's paper, a period of seven months, while in untreated control animals paralytic symptoms developed within four weeks.

Beyond the interest in this specific result, Dr. Manwaring's paper throws more light upon another important fact, and that is the difference between the cerebrospinal membranes and the true serous membranes of the body. The latter are very pervious and obtain protective substances from the blood proteins which easily reach them. The cerebrospinal membranes, on the other hand, are almost impervious to the blood proteins, and to help them fight infection biological protective substances must be brought into direct contact with them, that is, they must be introduced by means of trephine openings or a lumbar puncture.

Chemotherapy of Cancer.

The opinion has been expressed by one of the most eminent authorities on carcinoma therapy that if a suitable chemotherapeutic remedy could be discovered to act as a synergist to radium and the röntgen rays the conquest of cancer should be at hand. This synergism becomes indispensable because radio- and emanation-therapy exert at best but a local activity, and something is needed to attack the cancer cell through the circulation. At a recent meeting of the Naturhistorisch-Medizinischer Verein zu Heidelberg (*Münchener medizinische Wochenschrift*, January 16), held, however, before the publication by von Wassermann of his preliminary work with eosin and selenium, von Dungern expressed the belief that such a chemotherapeutic remedy may have been found in serpent venom, particularly in crotalin, which causes necrosis of rat sarcoma without injury to the host and which, tested in human patients hopelessly ill with cancer, in association with emanations, caused rapid regression of cancer nodes. In the discussion Czerny called attention to the toxin element which is essential to the activity of several biological substances recommended as hostile to the cancer cell. Here belong Coley's mixed toxins, Adamkiewicz's cancroin, and Schmidt's antimeristem. Crotalin should perhaps possess advantages over these artificial preparations. There is, however, considerable ambiguity involved in speaking of this class of remedies as chemotherapeutic, for these, along with trypsin, liver enzyme, etc., have not been thrown into the general circulation, at least in routine procedure. So that the new researches with eosin-selenium are alone to be regarded as strictly chemotherapeutic in type.

Ophthalmoplegic Migraine.

Under this and similar designations many cases have been described, all of which exhibit recurrent migraine accompanied by temporary paralysis of the oculomotor nerve. Other cranial nerves may or may not be involved. It is not often that opportunity is offered for determining the exact nature of these cases. At a meeting of the Tokio Medical Society, held last year, Shionoya reported a case with autopsy, from which it plainly appeared that the affection was something more than a mere neurosis (*Deutsche medizinische Wochenschrift*, December 14, 1911). The patient was a boy aged 16, who had suffered from recurrent ophthalmoplegic migraine for ten years. The interval, originally longer, gradually became of a month's duration, while in each crisis the paralysis persisted for two weeks, and at last became permanent. The patient, who was tuberculous, succumbed in time to his malady. Autopsy revealed a fusiform fibroma of the right motor-oculi nerve at its foramen of exit. There was a mild recent tuberculous meningitis. The attack of paralysis had been due evidently to periodical swelling of the affected nerve.

News of the Week.

Phthisis in Alaska.—According to the report of Dr. M. H. Foster of the Public Health and Marine-Hospital Service, nearly 50 per cent. of the population of Alaska are afflicted with tuberculosis. The report states that unless the ravages of the disease are checked both the white people and the natives will be wiped out ultimately. The report states that eye diseases are also prevalent.

Street Deaths Increase.—According to the report of the National Highways Association, deaths due to vehicular traffic during January, 1912, in the streets of New York City show an increase, as 29 persons were killed this January, whereas only 22 met death in this way last January. Statistics for

New York State show that 9 persons were killed in January, 1912, as against 7 for the same month of 1911. In New York City reports were received of 219 persons who were injured in street accidents.

Health of the Canal Zone.—The Department of Sanitation of the Isthmian Canal Commission reports that for the month of November, 1911, the total number of deaths from all causes among employees was 41. These were divided as follows: From disease 33 and from violence 8, giving the annual average per thousand of 7.85 and 1.90 respectively. The average death rate per thousand for whites was 6.62 and for blacks 8.27. For the same month during 1909 the annual average death rate per thousand from diseases among whites was 5.88 and blacks 11.31, giving a general average of 10.69. The deaths from the principal diseases were as follows: Amebic abscess of liver, 1; chronic nephritis, 1; dysentery, clinical, 1; hemoglobinuric fever, 2; lobar pneumonia 11; malarial fever estivo-autumnal, 3; tuberculosis, disseminated, 4; leaving 10 deaths from all other diseases and 8 deaths from external violence. No cases of yellow fever, smallpox, or plague originated or were brought to the Isthmus during the month.

The Tammany Antivaccination Campaign.—Although the Tammany Aldermen, at their meeting on January 30 again refused the appropriation requested by the New York Board of Health for $15,000 for the purpose of offering free vaccination to the people in the tenements, the Health Commissioner has renewed his application and announces that he will persist in the request until he receives the money. There have been nine cases of smallpox reported in Brooklyn thus far this year and an epidemic of smallpox may be expected if vaccination is not more generally practised. In 1902 and the years following when there was an outbreak of smallpox in the city, $115,000 was appropriated, and over 800,000 people were vaccinated, while for the past ten years there has been practically no vaccination in some sections of the city.

Health Reforms Demanded in St. Louis.—The Board of Health of East St. Louis, at its meeting on January 24, demanded that the city establish a garbage plant, erect and maintain a city hospital, and compel the physicians to report at once all births. The mayor was requested to have an ordinance drafted covering each of these demands and to have it presented to the council at once for approval.

Republican Club Discusses National Health Bureau.—The subject chosen for discussion at the Republican Club in New York on February 3 was the creation of a national bureau of health. Officers of the health boards of New York, Massachusetts, New Jersey, Pennsylvania, and Rhode Island, either by letter or in person, favored the creation of such a bureau. Among those who spoke in favor of the bureau were Prof. Irving Fisher of Yale, Dr. J. D. Bryant, Dr. Louis L. Seaman, President Polk of the New York Academy of Medicine, and Senator Owen of Oklahoma.

Lincoln Fund for the Negroes.—The Commercial Club of Omaha, Neb., has passed resolutions urging that the National Lincoln memorial fund, which amounts to about $2,000,000,, shall be expended for a hospital, industrial school, or model farm for negroes. The object of the resolutions is to head off a movement to use the money for the construction of a road from Washington to Gettysburg, to be known as the Lincoln Memorial Highway.

Gifts for Charity.—The will of Mrs. Catherine Neustädter of San Francisco, who died recently in New York, leaves $1,000,000 for the establishment of the Neustädter Home, an institution to be used for caring for convalescents and for the permanent amelioration of the condition of unfortunates by providing better housing conditions in model home dwellings within a radius of thirty miles from New York City Hall. The will also leaves $100,000 each to Mount Sinai Hospital and the United Hebrew Charities, $50,000 to the Educational Alliance, $10,000 to the Montefiore Home, $20,000 to the Home for Aged and Infirm Hebrews, $5,000 to St. John's Guild, and $20,000 to the Jewish Children's Sanitarium at Rockaway. The San Francisco institutions which are beneficiaries under the will are the following: Jewish Orphan Asylum, $20,000; Eureka Benevolent Society, $10,000; Children's Hospital, $5,000; Protestant Orphan Asylum, $5,000, and the Jewish Protectory and Aid Society, $5,000. An additional $5,000 has been subscribed toward the fund that is being raised for the new buildings of the Tuberculosis Preventorium at Farmingdale, N. J. Only $10,000 is now needed to complete the required $150,000.—The Julia F. Burnham Hospital at Champaign, Ill., has received a donation of $1,000.—A benefit for the hospital at Ware, Mass., has netted that institution $586.—The town of Springfield, Mass., has increased its annual appropriation for the Noble Hospital from $1,000 to $5,000.—The Melrose (Mass.) Hospital Association was given $5,000 under the will of Thomas W. Ripley. This has been filed in the Middlesex Probate Court at East Cambridge, Mass. The will of Edward O. Kinberg of Brooklyn leaves the bulk of his estate, valued at $75,000, to the Presbyterian Hospital. The twenty-second annual German Charity Ball, held at the Hotel Astor on the evening of January 24, netted $11,000, which will be divided among German charitable institutions. An anonymous donor has given $25,000 toward the fund that is being raised for the proposed hospital for animals in New York City. Of the $100,000 required $75,000 has already been raised. The Hospital Saturday and Sunday Association reports that the Dry Goods Trade Auxiliary has contributed $6,517 to the hospital fund. By the will of the late Anna Hertzog Carver of Philadelphia the sum of $50,000 is devised to the trustees of the University of Pennsylvania, the German Hospital, and the Jefferson Medical College, each in trust, and as a memorial to her husband, William Burton Carver, the income from the fund to be used for the endowment and maintenance of free beds in the hospital conducted in connection with the institution named with the proviso that these beds are to be utilized not only for the care of the sick but also for the instruction of students in medicine or others seeking medical instruction. Also the sum of $10,000 is bequeathed to the Hospital of the Protestant Episcopal Church. The Seney Hospital of Brooklyn, N. Y., has received $10,000 under the will of Roland D. Armstrong, the income of which is to be used for the maintenance of two beds. Mount Sinai Hospital, New York, has received a gift of $20,000 to be used for the extension of social service work. This makes $245,000 that has been received by this hospital during the past year

in the form of donations, legacies, and bequests. By the will of Thomas W. Ripley, the Melrose Hospital Association of Melrose, Mass., receives a bequest of $5,000. A bequest of $50,000 for the House of Mercy Hospital, at Pittsfield, Mass., is contained in the will of Mrs. Florence de Wolf Sampson. The annual Charity Ball has netted the Milwaukee Infants' Home and Hospital $2,500.

To Abandon the Columbia Hospital.—The House of Representatives has voted to abandon the Columbia Hospital for Women at Washington, D. C., because of the dilapidated condition of the building, which has been declared a firetrap, and instead places $20,000 in the hands of the Board of Charities to care by contract for indigent patients, who have hitherto been cared for by this institution.

The Boston Dispensary, probably the oldest in the United States, having been founded in 1796, has just issued its annual report, which shows that during the year 1911 41,591 patients were treated, and the district physicians cared for 10,865 patients in their homes. The pharmacy put up 87,180 prescriptions for 8,000 patients, for which no charge was made. The report contains a facsimile letter written by Dr. Oliver Wendell Holmes, applying for a position on the medical staff of the dispensary.

The Leominster Hospital in the town of Leominster, Mass., was opened on January 27.

State License Examinations in German Not Allowed.—The fact that in the State of Wisconsin Greek and Italian doctors are permitted to take examinations for license to practise through an interpreter and that the same privilege is not extended to German doctors has led to a discussion of the subject and to the adoption of resolutions by the local branch of the National German-American Alliance requesting the Governor of the State to take some action in the matter.

Assistant Registrar of Records Needed.—The Municipal Civil Service Commission announces that an examination will be held for the position of Assistant Registrar of Records in the Department of Health of New York City. The position requires not only that the incumbent be a duly qualified physician, but that he should have training and experience in statistical work. Information as to the time and place of the examination may be had by applying to the Municipal Civil Service Commission, 299 Broadway, New York City.

The International Congress on Hygiene and Demography will hold its fifteenth annual meeting in Washington, D. C., from September 23 to 28, 1912. President Taft is Honorary President of the Congress, Dr. Henry Walcott is President, and Dr. John S. Fulton is Secretary-General. In connection with the Congress, and in buildings especially erected for the purpose in Potomac Park, there will be an exhibit on public health in charge of Dr. Joseph W. Schereschewsky of the United States Public Health and Marine-Hospital Service. This exhibit will open early in September and will continue until after the Congress.

Medical Library Building Sold.—The Mott Memorial Surgical and Medical Library, which was the home of the late Dr. Valentine Mott and contains the books and instruments that were formerly Dr. Mott's, was sold on February 1 as the result of a friendly action brought by the heirs for a decree of sale in a partition action concerning the property.

Dr. Henry A. Christian has handed in his resignation as dean of the Harvard Medical School to take effect on September 1. He has taken this step in order that he may devote himself more fully to the work of the new Brigham Hospital.

Dr. Abraham Sophian of the New York Health Department, who went to Texas to assist in fighting the epidemic of meningitis in northern Texas, left for New York on February 3 bearing gifts in jewels and cash. The citizens and physicians of Dallas gave him a loving cup, and the citizens of Waco and several small towns presented him with various gits in acknowledgment of their gratitude for his services.

The Burlington County (N. J.) Medical Society held its meeting at Madison, N. J., January 17 and the following officers were elected: *President*, Dr. William P. Melcher of Mount Holly; *Vice-President*, Dr. A. L. Gordon of Burlington; *Secretary and Treasurer*, Dr. George T. Tracy of Beverly.

The Lee County Medical Society, which met at Opelika, Ala., on January 22, elected the following officers: *President*, Dr. George H. Cooper of Dothan; *Vice-President*, Dr. O. V. Langley of Camp Hill; *Secretary*, Dr. H. S. Bruce of Opelika.

The Spartanburg County Medical Society, at its annual meeting at Spartanburg, S. C., elected the following officers: *President*, Dr. A. I. Cudd of Spartanburg; *Vice-President*, Dr. W. H. Chapman of Whitney; *Secretary*, Dr. Rosa H. Gantt of Spartanburg; *Delegate to State Association*, Dr. W. W. Boyd of Spartanburg; *Censor*, Dr. D. R. Norman of Fairforest.

The Jefferson County Medical Society, at its annual meeting at Jefferson, Wis., elected the following officers: *President*, Dr. L. J. Bennett of Fort Atkinson; *Vice-President*, Dr. W. T. Clark of Fort Atkinson; *Secretary*, Dr. C. R. Feld of Watertown; *Delegate to the State Convention*, Dr. H. O. Caswell of Fort Atkinson.

To Educate East Side Mothers.—The statement of physicans that improper care and feeding are responsible for the death of 25 per cent. of the babies born on the East Side of New York City has led to the organization of a society to be known as the "After Care Circle." The work of the society will be done in connection with the Jewish Maternity Hospital and will consist in the instruction of mothers in their homes after they have left the hospital and in the feeding and care of their babies. A special nurse has been engaged for this work.

Talladega Infirmary Opened.—The new hospital at Talladega, Ala., was formally opened on January 16.

Milwaukee Hospital Addition.—The addition to the Milwaukee Hospital, which was built at a cost of $80,000, is about completed and will be ready for occupancy by May 1.

Civil Service Examinations.—The State Civil Service Commission announces that it will hold examinations on February 24 for the following positions: Bacteriologist to the Health officer of the Port of New York, for which women are eligible; first assistant veterinarian to the Department of Agriculture; veterinarian to the Department of Agriculture employed by the day; physician to the Erie County Lodging House; physician, homeopathic or regular. Application blanks and further information may be had by applying to the State Civil Service Commission, Albany, N. Y.

Mothers Begin Child Welfare Campaign.—The National Congress of Mothers will begin a

country wide campaign in the interests of the child. They have taken for their slogan "better babies, better parents, better country." Their work will be in the nature of a widespread educational campaign.

Boston Hospital Needs Funds.—Work has been halted on the new building of the Infants' Hospital which is in the process of construction near Harvard Medical School. It is stated that $90,000 is required to complete the building, which is very badly needed, as the old building is totally inadequate to meet the demands made upon it in the hot weather.

The Surgical Section of the Hartford Medical Society held its annual meeting on January 22 and elected the following officers: *Chairman*, Dr. Ansel G. Cook; *Secretary*, Dr. A. M. Outerson; *Treasurer*, Dr. Henry A. Martelle; *Fourth Member of the Executive Committee*, Dr. Arthur J. Wolff.

The First International Eugenics Congress will be held next summer at the University of London.

The Chattahoochee Valley Medical and Surgical Association, which held its semi-annual session at LaGrange, Ala., on January 10 and 17, elected the following officers: *President*, Dr. George M. Niles of Atlanta; *Vice-Presidents*, Drs. Velpeau Langley of Opelika, and C. S. Yarborough of Auburn; *Secretary and Treasurer*, Dr. W. J. Love of Opelika.

The Central Texas District Medical Society, which adjourned on January 10, elected the following officers: *President*, Dr. Edward Graves of Gatesville; *Secretary-Treasurer*, Dr. M. F. Connally of Waco.

The South Ontario and West Durham Medical Association, which met at Newcastle, Ont., on January 8, elected the following officers: *Honorary President*, Dr. S. J. Frotheringham of Toronto; *President*, Dr. D. Farncomb of Newcastle; *Vice-President*, Dr. Beith of Bowmanville; *Secretary-Treasurer*, Dr. J. F. Finnigan of Oshawa.

The Central Oklahoma Medical Association, which met at Enid on January 10, elected the following officers: *President*, Dr. S. N. Mayberry of Enid; *Vice-Presidents*, Dr. T. M. Adderhold of El Reno and Dr. C. R. Day of Oklahoma City; *Secretary and Treasurer*, Dr. W. W. Jones of Enid.

The Association Internationale de Perfectionnement Scientifique announces that its ninth Annual Congress will be held under the patronage of the French Government, from August 3 to 31, 1912, in the Balkans in Turkey, and in Greece. Further particulars may be had by writing to Head Office A. P. H., 12, Rue François Millet, Paris, XVI.

The Medical Society of the Missouri Valley will hold its twenty-fourth semi-annual meeting at Colfax, Iowa, on March 21 and 22, 1912. Dr. Charles Wood Fassett of St. Joseph, Mo., is secretary.

Obituary Notes.—Dr. Inslee Hopper Berry of New York City, a graduate of Cornell Medical College in 1890, died at his home January 30, at the age of forty years. He was visiting physician to the German Lutheran and Metropolitan Hospitals and the Northern Dispensary. He was also surgeon to St. Elizabeth and the Post-Graduate Hospitals.

Dr. Isaac S. Smith of Rodgers, Tex., died of cerebrospinal meningitis at his home January 16.

Dr. George Hemminger of Carlisle, Pa., a graduate of Detroit Medical College in 1860, died at his home January 20, at the age of 71. He was in the battles of Kelly's Ford, Brandy Station, the Wilderness, Spottsylvania, Cold Harbor, and Monocacy, and had been imprisoned at Danville and Libby. In 1865 he was paroled and was with Gen. Sherman in the grand review at Washington June 8, 1865.

Dr. Edward Fornias died at Philadelphia on January 22, at the age of 69 years. He was a native of Havana and was graduated from Hahnemann Medical College of Philadelphia in the class of 1880.

Dr. Peter H. Latham died of diabetes at Weatherly, Pa., on January 24, at the age of 62 years. He was graduated from the University of Maryland School of Medicine in the class of 1876. He was formerly Coroner of Carbon County and surgeon to the Lehigh Valley Railroad Co.

Dr. James S. Hickey died of endocarditis at Philadelphia on January 25 at the age of 57 years. He was graduated from Hahnemann Medical College of Philadelphia in the class of 1892. He was instructor of anatomy in Hahnemann Medical College.

Dr. George Friebis died suddenly at Philadelphia on January 26 at the age of 57 years. He was graduated from Jefferson Medical College in the class of 1879. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association, and he was a Fellow of the College of Physicians of Philadelphia.

Dr. J. Miller Moore of Union, S. C., died in New York City January 29.

Dr. Ralph E. Starkweather of Chicago, Ill., a graduate of the College of Physicians and Surgeons, Columbia University, died as the result of an injury January 22, at the age of 69 years. He was well known for his study and work for improving sanitary conditions and procuring the enactment of laws for proper sanitation.

Dr. Nathan D. Tobey of Salina, Kan., a graduate of the University of Maryland School of Medicine, Baltimore, in 1863, died suddenly at his home, January 19, at the age of 75 years.

Dr. Jacob Gerstl of New York City died at his home January 21. He practised in Harlem for over twenty years.

Dr. Atwell William Swett of Bangor, Me., a graduate of Darthmouth Medical School, Hanover, N. H., in 1863, died at his home January 15, at the age of 72 years. He served as surgeon during the Civil War, being mustered out with the rank of First Lieutenant and Brevet Captain.

Dr. Edwin W. Bennett of San Francisco, Cal., died suddenly January 10, at the age of 65 years. The cause of his death was disease of the heart.

Dr. Jesse K. McAfee of Dalton, Ga., a graduate of Atlanta Medical College in 1888, died at his home January 14, at the age of 81 years.

Dr. Samuel LaGrande Crane of Hartford, Conn., a prominent dentist, died at his home following an attack of acute indigestion. He was 82 years of age, and had practised his profession for 65 years.

Dr. Robert Schuyler Black of Ottawa, Kan., a graduate of the Medical College of Indiana, Indianapolis, in 1875, at one time president of the Kansas State Medical Society, died January 11, at the age of 69 years.

Dr. Leopold Burgheim died at his home in New York on January 24, at the age of 68 years.

He was born in Germany and was graduated from the College of Physicians and Surgeons of Columbia University, New York City.

Dr. Mary E. Scott of Denver, Col., died at her home after a long illness on January 12, at the age of 70 years.

Dr. Henry D. Averill of Bar Harbor, Me., a graduate of the Medical School of Maine, Portland, died in Steuben January 16.

Dr. Samuel Short of New York City died of septicemia in Bellevue Hospital on January 24, at the age of 39 years. He was graduated from the Long Island Hospital Medical College in the class of 1903.

Dr. Willey J. P. Kingsley died at his home in Rome, N. Y., on January 26, at the age of 82 years. He was graduated from the New York Medical College in 1855, and was Mayor of Rome in 1895.

Dr. Walter W. Johnson of Rochester, N. Y., died in a sanatorium in that city on January 26, at the age of 53. He was graduated from the New York Homeopathic College in 1887 and was a charter member of the Röntgen Ray Society of America.

Dr. James Samuel Hickey of Philadelphia, a graduate of Hahnemann Medical College and Hospital in 1892, died at his home January 26, at the age of 56.

Dr. Lyman Watlins of Blanchester, Ohio, a graduate of Ohio Medical University, Columbus, died at the Seton Hospital in Cincinnati January 21, at the age of 59 years.

Dr. Gilbert C. Greenway of Hot Springs, Ark., a graduate of the University of Maryland School of Medicine, Baltimore, in 1867, died at his home January 19, at the age of 68 years.

Correspondence.

VACCINE TREATMENT OF PNEUMONIA.

To the Editor of the Medical Record:

Sir:—During the past year I have had an experience with my cases of pneumonia which, if confirmed by other observers, would tend to show that pneumococcic vaccine is of value in treatment of this disease. Six patients treated with this bacterine within forty-eight hours of the initial chill were practically well within three days. Two were habitual drinkers with the most unfavorable prognosis. One was an infant of twenty-two months. These patients furnished pure cultures of the pneumococcus both from blood and sputum.

Two cases in which an infecting agent proved on culture to be the pneumobacillus of Friedlaender were not influenced. One of these went through the following course: lobar pneumonia, appendicitis (operated), pleurisy (operated), alveolar abscess, arthritis, peritonitis, death from exhaustion but with original infection.

In the pneumococcic patients treated after forty-eight hours with pneumobacterin the disease was apparently unaffected, but they developed no complications and none died. Cases mixed or septic were not directly influenced, though in all recovery took place. As I have had years in which all cases recovered and others in which many patients died, I would like to get the experience of others. My treatment has been to place the patient in bed with the affected side strapped with zinc oxide adhesive plaster over which a hot water bottle is applied. Saline solution, eight ounces every hour, and eight ounces milk and lime water, equal parts, every two hours.

Contrary to the usual method of using pneumobacterin, I have given 400,000,000 bacteria on three successive days and then quit. I wish the profession clearly to understand that I make no claims for this treatment, but ask the experience of others.

H. H. Sinclair, M.D., C.M.

Walkerton, Ont.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CANCER—X-RAY DIAGNOSIS OF PHTHISIS—HARVEIAN SOCIETY—SLEEPING SICKNESS—SATURDAY FUND—B. M. A. COUNCIL REFUSES GENERAL MEETING—OBITUARY.

London, January 19, 1912.

The Polyclinic resumed work after the recess on the 8th inst., when the members had the privilege of hearing Wassermann's recent research on cancer expounded by Dr. Bashford, who had just returned from Berlin. He reported that the German scientist had shown him the greatest courtesy and placed every information on the subject at his disposal. Following the line of thought associated with the name of Ehrlich, a direct attack on the cancer cells through the blood seemed to Wassermann a possibility. The rapid growth of cancer cells suggested that they must demand a great supply of oxygen and any interference with that supply would have a decided effect on the cells. For this purpose Wassermann proposed to employ selenium, introducing it into the neighborhood of the cancer cells and, if possible, into their very substance. Dr. Bashford thought that the idea of utilizing such an element as selenium in an eosin dye was characteristic of the Ehrlich school, and I agree with him that few not trained there would be likely to conceive it. It is on that idea that Wassermann has been working, and the results are interesting. The pink solution of eosin-selenium was injected into the vein of a mouse with a tumor. This colored the skin of the mouse, but in a few hours the pink had gone from the skin. The mouse was killed and examined, when it was found that the tumor was deeply stained—the tumor only. This result was constant. Further experiment proved that the injection can be repeated and in some instances the mouse may survive—for the solution is a virulent poison—and if it should survive the tumor may disappear in a definite manner. Wassermann experimented on mice before Dr. Bashford, who said the injection killed four out of the six, but the two survivors were cured, and this, he was informed, was the certain result in the mice which could bear the treatment. Wassermann makes no claim of having found a cure for cancer, but only to have proved that a chemical substance injected into the blood stream may kill certain diseased cells without injuring the other tissues. This is a step forward, as previously such a result would not have been deemed possible. I do not know the precise combination of eosin and selenium; still less can I send you a formula for it. Dr. Bashford seemed to know no more than that it was difficult to prepare. But chemists will no doubt give us all information and, if required, the preparation will soon be procurable. But for the present it is only the workers in the pathological and biological laboratories who will be wanting it. The effect on other animals may not be the same as on mice, and it is too deadly

a poison to be tried on man. But it may point the way for the discovery of some other chemical while the biologists are searching for some method of intensifying the susceptibility of tumor cells to interference with their supply of oxygen or increasing their avidity for that element.

Dr. Harrison Orton has contributed to the Medical Society of London a paper on the *x*-ray diagnosis of pulmonary tuberculosis. He believes this method may show the presence of the disease even in the early stage, but he does not pretend to rely upon it for that purpose. He puts it forward as a useful additional aid to other methods, no one of which can be regarded as by itself alone infallible. The *x*-rays bring into play the most highly developed sense of sight to control touch and hearing. He acknowledged that every detail of the examination must be carefully carried out by a skilled observer and followed by the equally skilled interpretation of a satisfactory negative. Perfunctory examinations and imperfect technique he held responsible for errors which had tended to discredit the method. This we may readily admit, not merely for chest examinations but for all cases in which diagnosis by *x*-rays has been employed. We must acknowledge that the technique requires time and the interpretation of the appearances is no less exacting, so that the busy practitioner cannot get as much assistance from the rays as specialists seem to anticipate. Dr. Orton described some of the normal appearances when the screen was placed on the anterior and posterior surface of the chest, the *x*-ray tube being, of course, on the opposite side. There were three vertically disposed zones—the middle one dark, corresponding to the shadows cast by the vertebral column, sternum, and mediastinal contents (including the heart). The lateral zones were clear and corresponded with the areas of the lungs. These were crossed by the curved shadows of the ribs and the rather denser ones of the clavicles bounding them above, while laterally were the walls of the thorax, and below two dark dome-shaped shadows, which rose and fell with the respiration, and corresponded with the diaphragm. With the screen the ribs form a prominent feature, hardly noticed when at the back on account of its distance. So the heart is more distinct in front as nearer to the anterior surface. In tuberculosis definite shadows were cast by diseased portions of lung, and here will be seen (1) dimness at one or both apices, with failure to brighten on deep inspiration; (2) restricted movement of diaphragm, as a rule in the lower part of the excursion; (3) in most cases the heart is smaller and more vertically situated than normally.

The Harveian Society held its annual meeting on the 4th, when the election of officers for the ensuing year took place. The retiring president, Mr. Ernest Lane, gave an address in which, having first referred to the work of the past year, he read an extract from a journal of 1835 on the appointment of medical officers for the poor, and then passed to consider the new Insurance Act, particularly as regarded the number of patients that every one taking office under it would have to attend and the proposed fee for the service. He also spoke of the financial prospects of the voluntary hospitals as they are likely to be affected by the new act. On concluding his address he vacated the chair and his successor to the presidency, Dr. H. J. Macevoy, was duly installed.

The Council of the B. M. A., acting on legal advice, has resolved not to call the special general meeting to discuss the proposed vote of censure. They say that the counsel who was consulted on the framing of the constitution is of opinion that the vote of censure does not come within the sort of questions that can be submitted to an extraordinary general meeting, but it was a matter that could be dealt with by the representative body. It is therefore intended to convene a meeting of this body about the last week in February—a month after the ordinary quarterly Council meeting of January 31. This will give time for the Council to reflect and resolve on its defence—and also to its constituents. The discussion of the matter goes on with unabated energy and no less strong language. It certainly seems a curious thing for an elected committee to fling counsel's opinion in the face of their constituents, instead of resignation—the more especially in reply to a requisition signed by more than 500 members. And what a light it sheds on the care taken in reorganizing the constitution to render its vaunted democratic character null and confine all power to the inner circle. The dispute about payment goes on in all the papers. Mr. Lloyd George has been trying to terrify the taxpayers by suggesting that to agree to the doctors' demands would oblige him to put another 6d. on the income tax.

Letters have arrived from members of the Chartered Company's Sleeping Sickness Commission now in Northwestern Rhodesia, which say that Dr. Kingborn has transmitted trypanosomiasis by means of the *Glossina morsitans*.

The Hospital Saturday's Fund collected last year £37,065, making 1911 the largest annual amount obtained in any year. A further sum, £8,456, was received for the Surgical Appliance and the Distribution Committees, which have separate bank accounts, making a total of £45,521.

The death of Dr. Sophia Jex-Blake on the 7th inst., nearing the close of her 72d year, forcibly recalls the stubborn fight made for the right of women to become practitioners of medicine. Miss Jex-Blake was one of the most active combatants in the campaign and, after years of struggle, came out victorious. She founded the Edinburgh and the London Schools of Medicine for Women. Though she had retired for some years, she was sometimes to be seen in medical meetings, and kept up her interest in the profession to the end of her eventful life.

Sir Ch. O'Grady Gubbins, M.D., Senator in the South African Legislature, was a Dublin graduate who went out with troops to the Zulu war and afterward settled in practice in Natal. Eventually he gave up medical work for politics, in which he quickly made his mark, and some six years ago was Colonial Secretary and Minister for Education in Natal, his term of office being signalized by the compulsory educational act and the establishment of the university. On the union of the colonies in the South African Parliament he became a senator and minister. Last year he was knighted.

Surgeon-General Sir J. Andrews Woolfryes, K.C.B., C.M.G., Honorable Physician to the King, died on the 12th inst., at the age of 88. He qualified in 1846 and entered the Army Medical Service the following year. In the Ashanti war, 1873, he was P.M.O. and present at several battles. He was also in the Kaffir war, 1877, and later in the Zulu campaign. He was often mentioned in despatches, and received medals and the orders stated above. He retired in 1883.

Dr. Ch. Warden, Justice of the Peace of Birmingham, where he was consulting surgeon to the Hospital for Women and Children, to the Orthopedic, and to the Ear and Throat Hospitals, died on the 13th inst., in his 85th year. He took the double qualification in London in 1850-51, and in the latter year proceeded to M.D., Aberdeen. He had occupied other important positions in Birmingham, both professional and public. He contributed occasionally to the medical societies and journals.

Dr. Edmund Downes, who died on the 11th inst., aged 60, at Eastbourne, where he practiced a few years but had been for some time an invalid, was better known for his work as a medical missionary in Kashmir. He contributed papers to the missionary conferences in Calcutta (1882) and London (1894). In his early days he served for a time in the Army Medical Department. He qualified in 1876, L.R.C.P. and M.D., Brussels. Later he took the F.R.C.S.

Mr. James Taylor, Justice of the Peace for Chester, in which city he died on the 14th inst., aged 72, after practicing there many years, retired about four years ago. He had served the infirmary there as surgeon and became consulting surgeon to that as well as the Wrexham Infirmary. He had been president of the Chester Medical Society, the Obstetrical and Gynecological Society, and held in turn all other offices his colleagues and fellow-citizens could confer. He qualified in 1864 and took F.R.C.S., England, in 1882.

Dr. Robert W. Ceely has died at the age of 65. He qualified in 1867, and after considerable experience of insanity as deputy medical superintendent of Worcester Asylum, and later as superintendent at Wandsworth, settled in practice at Kilburn.

Mr. Alfred Wolff, who died on December 26, had long enjoyed a large practice, chiefly among the Jewish community, of which he was a prominent member. He also found time for a good deal of occasional journalistic work. He retired about a year ago.

Report of a Case of Belladonna Poisoning in a Child, Seven Years of Age. R. E. Coughlin.

The Modern Conception of Medicine.—R. C. Cabot discusses six tendencies in modern medical service: First, the tendency to change from the individual point of view (in the relation of doctor and patient) to the social point of view; second, the tendency to change from a purely physical conception of man to a psychophysical conception; third, a tendency to split up into specialties and away from the conception of the general practitioner; fourth, a tendency to democracy in medicine, the democratic relation of the doctor to the public and to his patient; fifth, the tendency to be positive and not speculative in the study of the medical science, and last, the tendency toward a preventive and hygienic rather than a merely curative attempt in relation to one's problems. Every sick person is himself a symptom of something wrong in the community—either in the industrial, economic, or moral conditions surrounding the patient. The psychical elements of human nature cannot be disregarded without peril. Specialism in medicine calls for team work among specialists, and for much closer team work than has been customary. The doctor used to be more like a virtuoso, a great musician. He is to-day far less of a virtuoso, and far more of a reliable, efficient workman, of a type of which there are many, no one man being necessary for any one case. Many men are able to do about the same grade of work, are equally reliable, equally efficient. The exceptions are in surgery, where the virtuoso still holds his place, where a man may really save a life; and also in neurology, where there are still virtuosos, great personalities, whose personality counts for everything in relation to nervous patients and where another equally well-trained man will not do. There is a need for more speculative spirit in medicine, closely controlled by empirical findings.

Gastric Symptoms in Biliary Disease.—By H. Lilienthal. (See MEDICAL RECORD, January 27, 1912.)

Criminality and Morphinism.—T. D. Crothers states that morphinists are seldom seen in courts for brutal crimes like the alcoholics. The crimes usually committed by morphinists are against property and character, and are based upon impulse and selfishness. Kleptomania, forgery, swindling, and misdemeanors of a minor class, with or without purpose, are common. One of the most marked phases of morphinism, which probably appears in most cases, is the pleasure victims take in concealing their motives and conduct. They have a mania for leading a double life and enjoy the deception and mask which they draw about themselves. Often there is egotism which makes them dangerous as witnesses, because of their positive dependence on impressions that may be fleeting and uncertain. In addition to this, the morphinist has a constantly increasing diminished ethical sense.

Borderline of Medicine and Surgery.—By J. E. Moore. (See MEDICAL RECORD, January 13, page 88.)

Therapeutic Utilization of the Bile Tracts.—By L. L. McArthur. (See MEDICAL RECORD, January 27, 1912, page 188.)

Nauheim Treatment of Heart Disease.—H. Schoonmaker states that this treatment is indicated in any valvular disease except mitral stenosis, providing the functions of tonicity and contractility of both myocardium and arteries are tangible: that is, in cases in which myocardial compensation is not wholly lost, and arteries and capillaries are not stiffened or degenerated beyond the power to respond to external stimulation. It is indicated in mitral stenosis if the heart at its best, under the embarrassment of the stenosis, is able to maintain a fair cutaneous and pulmonary circulation. It is indicated in myocarditis without valvular lesion, under the same conditions as in valvular disease. It is indicated in angina pectoris if the same essentials are present. In a word, it is indicated in any case in which the cutaneous vessels are amenable to at least a fair degree of dilatation and at the same time the heart possesses sufficient reserve to adjust itself to such change in the blood current.

Traumatic Dislocation of Both Hips.—A. E. Chace points out the extreme rarity of this condition and adds a report of one case to the forty that he has found reported in the literature.

Study of Eosinophiles by Arneth's Nucleonalytical Method.—J. F. Hultgen concludes that the eosinophiles show no progressive development from monomorphism to polymorphism, except in leucemic conditions. The five classes of eosinophile nuclei occur constantly with remarkable uniformity under the most varied circumstances. One may accept class C, containing a distinctly bilobed, or hipartite, nucleus as the normal eosinophile, as the one

occurring constantly and with regular predominance in all persons, well or unwell. Arneth's neutrophile picture is applicable to the eosinophiles, but it merely indicates a constant percentage composition of the eosinophile contingent of the leucocytes. Arneth's eosinophile blood picture exists, but it is only a statistical fact and not of any practical biological significance. Ehrlich's theory that the adult eosinophile is derived from a prototypic eosinophilic myelocyte is not supported by the author's investigations. Commonly accepted criteria as to the youth of any given leucocyte must be amended. The morphological varieties of eosinophiles depend upon primordial, genetic causes. They are not a product of development. Since the morphology of the nucleus bears little or no relation to the origin, size, age, or function of these eosinophilic leucocytes, the nucleoanalytical method of Arneth lacks a biological foundation, and is, therefore, not applicable to these cells.

Inheritance of Harelip and Cleft Palate.—A. T. Hawes reports the case of a woman who had a child born with harelip and cleft palate. Subsequently she gave birth to two normal children, and then gave birth to twins, both having the deformity. There was the history of the deformity in a paternal uncle. The twins were attached to two separate placentæ. The cause could hardly be one that affected the placenta unless it happened to affect both. The theory of maternal impressions could hardly be held, because after the birth of the first baby with harelip the mother worried continually lest the second baby should have the same deformity. A normal baby came forth. After the second healthy baby she dismissed the subject from her mind and during this pregnancy had not worried or given the subject of deformity any thought.

Belladonna Poisoning.—R. E. Coughlin reports a case of this condition in a boy seven years of age, resulting from the administration for enuresis of the tincture of belladonna in ten-drop doses three times a day for one week. The symptoms of poisoning were nausea, hallucinations, dilatation of the pupils, and flushing of the face. Recovery followed twelve hours after discontinuance of the drug and the administration of a dose of castor oil.

Journal of the American Medical Association.

January 27, 1912.

Medical Ideals.—W. W. Anderson states that only in the department of major surgery is the medical art following closely in the footsteps of science, because its results are constantly reviewed and criticized by the profession, because it commands a fee that supplies the means for good work, and because of its limited field which can be cultivated. The same is true also to a certain extent of the other specialties, and, while a broad general knowledge is always necessary, the times demand even more insistently that, while the physician broadens his general vision, he should narrow his field of work.

Section of Posterior Spinal Nerve-Roots.—R. Winslow and I. G. Spear report two cases of posterior nerve-root section, one for the relief of tabetic gastric crises in which the posterior roots of the seventh, eighth, ninth, and tenth thoracic nerves were divided; the other of athetoid and choreiform movements in a boy aged seventeen years in whom several posterior roots from the lumbar enlargement on the left side were severed. In both cases there was uninterrupted recovery from the operation, and the vomiting was relieved in the first case and the athetoid movements were suppressed on the left side in the second, though they have, since the operation, increased on the other side.

Tonsillectomy with the Tonsillectome.—J. C. Beck describes a method of tonsillectomy which is performed with one instrument—the tonsillectome. This is a Pierce-Miller snare, modified by having a small but heavy fenestrum at the end, very much like the ordinary Vedder tip, through which the tonsil is pushed and everted. The wire loop is hidden in the slit of the fenestrum and is contained as a twisted stylet in the cannula.

Experimental Therapeutics.—T. Sollman states that the scientific pharmacologist is crippled by the paucity of exact scientific records of the effects of drugs on the human subject. These records must be supplied by the clinician, but the pharmacologist may aid him by valuable suggestions. Both clinical and laboratory studies are necessary, however, for the fullest results. Observations on the human subject cannot be as fully controlled and the problems analyzed as they can be in the animal. Experimental therapeutics is not a new subject. It is essentially the study of the effects of drugs under abnormal conditions, which is one of the ancient problems of pharmacology which has come lately more to the front.

Action of Drugs in Pathological Conditions.—W. Salant points out that the discovery that the reaction of the cell to chemical substances may be modified or even completely reversed by a change in one or more elements or radicals of the molecule is one of the leading advances influencing modern therapeutics. Experimental evidence of late years indicates that the reaction of the cells to foreign substances may be quantitatively and even qualitatively different under changed conditions of environment or morphological, chemical, or physical alterations, and these may bring about corresponding variations in pharmacological action. Facts are quoted showing that the selective action of drugs may be at least quantitatively modified by morbid changes.

Constitutional Inferiority and Its Psychoses.—C. P. Oberndorf classifies the conditions coming under the general head of constitutional physical inferiority. It does not include cases of mental debility or high-grade imbecility. The author recognizes two types as properly falling under this head—qualitative and quantitative. The qualitative inferiors possess many characteristics often found in men of genius and successful achievement, but they lack the determination and poise to complete their brilliantly though impulsively conceived plans. They are not mentally defective, but exhibit a defect of kind, not of amount.

Suprapubic Drainage Tube.—A. H. Peacock describes a tube for suprapubic drainage in cases of obstruction of the prostatic urethra when prostatectomy is refused. The tube is inserted through a brass plate fitting the abdominal surface over the bladder and held in place by tapes or elastics. The outer projecting portion of the tube is connected by a rubber tube to a bag, bottle, or other receptacle. The device cannot be compared, he says, in its results with a prostatectomy, but there are cases met with by every surgeon in which it can be resorted to. The suprapubic cystotomy required can easily be done under local anesthesia.

Hospital for Contagious Diseases.—A. C. Haven describes the aims that should be followed in planning such a hospital.

Poliomyelitis in California.—F. F. Gundrum reports

the epidemics of the disease that prevailed during 1910 and 1911, when there were 120 and five cases respectively. In 91 per cent. of the cases no history of contact with other cases could be obtained.

Delayed Diagnosis in Pulmonary Tuberculosis.—E. A. Gray emphasizes the facts that no certain diagnosis of pulmonary tuberculosis can rest on symptomatology; that error is bound to result in the absence of thorough physical examination, and that error means delay and disaster to the patient.

Pyloric Obstruction in Infants.—By W. B. Lewitt and L. Porter. (See MEDICAL RECORD, Vol. 80, page 108.)

Coleman-Shaffer Diet in Typhoid Fever.—B. R. Krohn states that this diet is one of high caloric value sustained in the main part by three articles of food, namely, lactose, cream, and bread and butter. The diet is a practical one and well borne by the patient. The nutrition of the patient remains in all but the most severe cases unusually good. Most cases show a slight loss in weight. The period of convalescence is shortened, the return of strength is rapid and the lassitude and enervation commonly seen after a serious illness are for the most part absent and replaced by a hopeful, well-nourished condition, rendering the patient anxious to return to his duties. In the thirty cases observed complications were rare and there were no deaths.

Blood Pressure in Patients with Relaxed Abdominal Musculature.—F. W. Birtch and T. G. Inman conclude that it may be normal to have a slight systolic fall of blood pressure on standing after lying down in healthy individuals who are not undergoing active muscular training. Patients with relaxed abdominal musculature and enteroptosis, not showing subjective symptoms, have at least the diastolic pressure sustained on change of position and it may be assumed that the vasomoter mechanism is competent. Patients with relaxed abdominal musculature and enteroptosis with circulatory symptoms show both a systolic and a diastolic fall on standing after lying. The neuropathic symptoms found in these cases are not due to the malposition of the viscera nor can they be placed among the neuroses. They are entirely dependent on the cerebral anemia. The circulatory changes, while the cause of the symptoms, are not the primary etiological factors, but are second to the great muscular atony, the cause of which is yet unknown.

Secondary Anemia in Panama.—J. P. Bates concludes from his study that the old idea of tropical heat producing anemia is incorrect and that anemias are almost always the result of several causes combined, such as malaria, uncinariasis, and malnutrition. The name to typical anemia is a useful one and should include all secondary anemias of the tropics. The term malaria cachexia should be given up, as it usually directs effort along wrong lines of treatment. Uncomplicated malaria, moreover, tends to establish a relative immunity and does not produce a severe secondary anemia unless complicated with semistarvation. Uncinariasis may cause a severe grade of anemia, but here malnutrition is largely a contributing cause. Malarial fever and uncinariasis together always produce a severe secondary anemia, uncinariasis being the more responsible. Insufficient food and food of poor quality are the most important contributing causes of tropical anemia, which causes are usually in direct proportion to the poverty of the people. Splenic enlargement is primarily due to malarial infection and the ultimate changes experienced are probably influenced by intercurrent disorders. Treatment of these secondary anemias should, regardless of previous malaria, be directed to the hookworm and to the improvement of food and nutrition.

Early Diagnosis of Tuberculosis.—C. W. Coutant makes a plea for the training of physicians in the ability to recognize tuberculosis in its earliest stages.

Iodine in Smallpox.—C. S. Rockhill reports that he has used a 10 per cent. iodine and 90 per cent. glycerine mixture painted over the pustules of smallpox with very satisfactory results. It dries the pustule, causes absorption of the toxin and arrests the destruction of tissue, thus preventing the usual disfigurement. It has shortened the duration of the hospital stay from twenty-five to thirty days under the old treatment to eight to fifteen days. The pustules on the face may be opened with a sterile instrument and touched up with tincture of iodine. Eighty-five patients have been treated by this method within the past year, with 100 per cent. of recoveries and an average stay in the hospital of twelve days.

Method of Incubation.—J. H. Schrup describes an incubating device which he finds satisfactory and which can be readily improvised. He pours into a vacuum bottle water heated a little above blood heat and suspends the incubating tube by a thread inside the bottle and keeps the bottle tightly corked. If advisable a thermometer can be inserted through the cork. Almost any of the vacuum bottles on the market will answer the purpose, providing the cork fits closely. The loss of heat can be easily corrected if necessary by adding a slight amount of hot water every twelve hours. It is advisable to have the temperature at 100° F. in the beginning and to have the usual rubber cap over the tube to prevent the entrance of moisture.

The Resources of Surgery in Certain Emergencies. C. A. Ballance.
Sensory Disturbances from Cerebral Lesions. H. Head and G. Holmes.
Salvarsan in Syphilis. W. Evans.
On the Practical Results of the Recent Advances in the Diagnosis and Treatment of Syphilis. J. H. Sequeira.
Intestinal Myiasis. E. A. Cockayne.
Double Coxa Vara with Other Deformities Occurring in Brother and Sister. L. E. Barrington-Ward.
The Functions of the Tonsils and the Appendix. K. H. Digby.

Surgery in Emergencies.—C. A. Ballance cites illustrative cases showing the urgent relief demanded of surgery in the following conditions: Intestinal obstruction, peritoneal infection, acute appendicitis, abscess of the brain, gangrene of the extremities, calculous anuria, renal hemorrhage, internal hemorrhage, ruptured spleen, hemorrhage of the heart, wound or tuberculosis of the pulmonary artery, and some cases of intracranial hemorrhage.

Sensory Disturbances from Cerebral Lesions.—By H. Head and G. Holmes. (See page 200.)

Salvarsan.—W. Evans concludes from his experience that salvarsan is a rapid, safe, and effective remedy in syphilis.

Advances in the Diagnosis and Treatment of Syphilis.—J. H. Sequeira states that the early diagnosis of syphilis is of the utmost importance (*a*) to prevent the spread of the infection and (*b*) for efficient treatment. Treatment should be begun in the primary stage. There should be no waiting for secondaries. A doubtful chancre should be examined for the *Treponema pallidum*. The Wassermann reaction is of the highest utility in the diagnosis of secondary and tertiary eruptions. Treatment by mercury is undoubtedly efficacious. Nearly every case is influenced. After eight or more courses of injections 21 per cent. of the patients still have a positive Wassermann reaction. As regards salvarsan the danger is not great in properly selected cases. With rigid precautions taken in the preparation of the injections and with an aseptic technique the intravenous method has many advantages. The use of redistilled saline eliminates the pyrexia, rigors, vomiting, and other unpleasant symptoms in nearly every case. The immediate effects of salvarsan both on the clinical manifestations of the disease and on the Wassermann reaction are far more rapid than are those of mercury. The ultimate effects in primary syphilis are remarkable; in early cases the secondary stage may be aborted. The effects in well-developed secondary syphilis are less

striking and relapses certainly occur, and it remains for time to show the permanence of the results. In tertiary syphilis healing is extraordinarily rapid, but the Wassermann reaction is difficult to alter and relapses are likely to occur.

Intestinal Myiasis.—E. A. Cockayne states that in this condition the larvæ of numerous species of flies have been found. Their presence usually causes only slight symptoms, and even in cases where thousands of larvæ are passed those symptoms most common are anorexia, nausea, colicky pain, and constipation or diarrhea. In the more severe cases there may be vomiting, hematemesis, and diarrhea of dysenteric character. Nervous symptoms such as headache, vertigo, and epileptiform convulsions, which ceased with the expulsion of the larvæ, have been observed in a few cases.

Double Coxa Vara in Brother and Sister.—L. E. Barrington-Ward states that the two children presented a peculiar collection of skeletal deformities for which it was difficult to find a satisfactory etiology. The girl, aged nine, came under observation for a well-marked double coxa vara. She had had pains in the back and an alteration in her gait dating back eighteen months only. It was found that besides the hip affection she had abnormally short arms, many joints that were enlarged or creaked on movement, and eversion of the feet. Systematic examination of the bones with the *x*-rays revealed deficient, unequal, and in some cases divided development of many of the epiphyses. Inquiry of the parents elicited the fact that a younger brother, aged six and one-half, had lately shown signs of lameness. He was admitted to the hospital and was found to have double coxa vara of a milder degree, and also a forward luxation of the upper ends of both radii. With the *x*-rays it was seen that ossification in most of the bones was considerably advanced for his age.

The Functions of the Tonsils and the Appendix.—K. H. Digby deals with a group of lymphatic structures whose antibacterial activity is not commonly considered, and, indeed, is hardly recognized. These lie close to the surface of the body and can be called the subepithelial lymphatic glands. In this group are included the tonsils, nasopharyngeal, faucial, and lingual; the solitary follicles of the intestine, Peyer's patches, and the vermiform appendix. The author advances the hypothesis that these particular lymphatic structures protect the body again chance infection by a process of continual autovaccinations. Any bacteria in the vicinity are attracted by positive chemotaxis through the overlying epithelium into the lymphatic nodule. The bacterial attack, having been invited in a region most favorable to the defensive mechanisms of the body, is nearly always repulsed. In accordance with that overproduction which is so characteristic of biological response, specially trained lymphocytes and a great excess of specific bacteriolysins and antitoxins are produced. These enter the general system and lessen the risk of a successful bacterial infection at a more vulnerable part. Thus more or less immunity against organisms is acquired by the individual without his obviously suffering from disease. On rare occasions the lymph nodule is overcome and the disease develops; but the body has meanwhile become better able to withstand a general invasion.

Omentopexy for Ascites Due to Hepatic Cirrhosis.—R. Morison states that the steps of this operation are as follows: 1. Open the abdomen from the ensiform cartilage to the umbilicus. 2. Introduce the hand into the abdomen and project a finger against the anterior parietes in the middle line three inches above the pubis. 3. Make a small incision on to the finger tip, and through this introduce a long, small glass drainage tube into the rectovesical or rectouterine pouch. 4. Dry the abdominal cavity and scrub the peritoneum with mops. 5. Suture the omentum to the anterior parietal peritoneum across the abdominal wall and close the upper abdominal wound. 6. Apply an antiseptic dressing over the wound and tube, and over this, from above down to the tube, a series of long circular strips of adhesive strapping, with the object of keeping the parietal in contact with the visceral peritoneum. 7. The tube, now exposed through the dressings, is surrounded with a sheet of dental rubber perforated to grasp it below the collar on it, and the separated tube dressing is wrapped up in the india-rubber sheet.

Radical Cure of Hernia.—H. H. B. MacLeod emphasizes the fact that the treatment of all forms of hernia is essentially the same, and that the great underlying principle is to find the neck of the sac and to occlude it thoroughly. One may then do what one pleases with the other parts, varying the detail according to circumstances, and putting in such supporting and obliterating sutures through canal and rings as one's experience may determine.

Perforated Esophageal Ulcer.—J. Miller reports a case of this condition complicated by pyopneumothorax. Probably at least forty-six have been recorded up to date, including the author's. The most typical and constant symptoms of the condition are: Pain, which is severe and comes on immediately after food, the site of the pain being at the lower end of the sternum and a little to the left of it. Pain is also felt between the shoulders. Vomiting is the next most constant symptom. Dysphagia is present in more than half the cases. It is due to reflex spasm of the muscle of the esophagus from pain and it is the main diagnostic point differentiating the condition from gastric ulcer. Hematemesis is also a very common symptom. Perforation has occurred in eight cases—thrice into the right pleural cavity, once into the left (author's case), once into both pleural cavities (in each case with pneumothorax), once each into the aorta, pericardium, and lesser omental sac. The ulcer is usually single. It may extend into the stomach, and independent ulcers may occur in the stomach or duodenum (author's case). The situation is usually close to the cardiac orifice, and the right posterolateral wall appears to be the commonest site. The condition is usually found in middle life. As regards sex, of forty-five cases in which the sex was specified thirty-one were males and fourteen females. This preponderance of the ulcerations in the male corresponds, Miller holds, to what one knows of duodenal ulcer.

Typhoid Fever and Cholecystitis.—J. McMillan reports a case illustrating this association. The more important points are summarized as follows: 1. The presence of almost continuous constipation throughout the whole course of an ordinary typhoid illness. 2. The development of inflammation of the gall-bladder during convalescence, about the eighth week of illness. 3. The development of peritonitis forming adhesions between the gall-bladder and the colon. 4. The presence of *Bacillus typhosus* in pure culture. 5. The presence of a few gallstones, consisting of cholesterin and mucin.

Fibromyoma of the Stomach.—D. G. Cheyne reports a case of this condition which produced no symptoms and was discovered at the operation performed for what was

thought to be a subperitoneal fibroid or an ovarian cyst with a long pedicle.

Treatment of Damaged Intestine Without Resection.—H. B. Angus notes that frequently when doing emergency work one meets with an intestine which is torn, gangrenous, perforated over a limited area; or, after separating adhesions, free oozing is so persistent as to necessitate immediate treatment. In many cases of this kind resection appears to be the only resource, but if the patient is old and feeble, exhausted, or suffering from severe shock time is an important consideration, and the following simple method will be found most useful: Where there is a perforation—for example, from a bullet wound—a suture or two of chromicized catgut passing through all the coats approximates the edges of the rent; then with Pagenstecher's thread the adjacent sides of the damaged area of intestine are brought together by means of a Lembert suture—either continuous or interrupted—thus enclosing the weak spot. At first sight it appears as though obstruction would result from the kinking of the bowel, but this complication has not ensued after repeated trials. The method is simple, and occupies a short time as compared with resection and subsequent anastomosis.

Solid Carbon Dioxide in the Treatment of Hemorrhoids.—H. G. Anderson recommends the use of solid carbon dioxide in the treatment of small uncomplicated internal hemorrhoids.

Ruptured Liver and Right Kidney.—G. R. Girdlestone reports a case presenting the following points of interest: (1) The severity of the injury: The kidney was ruptured completely away from its pelvis and vessels and partially split; and the liver was extensively torn, and a portion completely detached. (2) The fact that the renal vessels were only bleeding comparatively slowly suggested a wonderfully efficient reaction. (3) The slowness of the pulse at the time of admission and the slowness of its rise. This is accounted for by rupture of the suprarenal with absorption of its secretions. (4) The capability and activity of the peritoneum in dealing with a considerable quantity of blood and exudation.

Acetyl-Salicylic Acid in Typhoid Fever.—G. Chambers states that the exhibition of acetyl-salicylic acid in small doses, 3 to 5 grains every four hours, combined with tepid or hot sponging, is generally an effective means of lowering the temperature. The exhibition of the drug in this dosage to typhoid patients does not alter the blood pressure or produce any appreciable ill effects. The skin remains moist, and in some cases there is profuse sweating. The greatest effect on the temperature is obtained by sponging the patient about half an hour after the administration of a dose of the drug, in this way combining the antipyretic actions of the medicinal and hydrotherapeutic agents.

Cast of Bladder Passed per Urethram.—J. M. Bartlet reports the case of a woman who passed a cast of the bladder studded with calculi.

Correction of Refractive Error for Microscopic Work.—Sir W. B. Leishman has devised a means whereby the microscopist having a refractive error may work at the microscope without wearing glasses. The lens necessary to correct the error of refraction of the eye commonly used is fitted accurately into the center of an aluminum carrier, so constructed as to form a cap which may be placed over the microscope ocular. In the case of a lens with cylindrical correction for astigmatic error the vertical meridian is permanently marked on the carrier by means of an arrow. As most workers employ oculars of the same maker, the external diameter of which is approximately the same, the cap may be made to fit them all by arranging to have the internal diameter adjusted to fit the largest ocular used.

Berliner klinische Wochenschrift.

January 15, 1912.

The Photodynamic Action of Fluorescent Substances.—Nagelschmidt, apropos of the recent use of eosin in cancer therapy, sums up our previous knowledge in this province. Eosin is a fluorescent substance which is able to induce biological reactions in the light only. In general the behavior of fluorescent substances when activated by light differs markedly with the substance, and there is no parallelism between fluorescence and photodynamics. In 1900 the discovery was first made that if a mouse was injected subcutaneously with an eosin solution and then exposed to the light necrosis of the ears developed. Since that period eosin has been studied extensively from this viewpoint, and other fluorescent substances have been studied and found to possess similar properties. These substances include chinolin red, phloxin, erythrosin, and fluorescin. It was at first hoped that this property of fluorescent substances could be utilized in the light treatment of disease, and especially in radiotherapy and emanation therapy, but it was quickly learned that the outlook in this direction was barren. The changes which take place when tissue cells are thus sensibilized to light are extremely complex; so much so that some positive therapeutic effects occur only in the dark, just as others require light for their manifestation. It has been shown that oxygen must be present in the tissues before light is able to activate the cells of an eosinized animal. The use of eosin in cancer therapy is the result of a decennium of study.

Polyneuritis Luetica.—According to Plehn, genuine polyneuritis due to the toxins of syphilis is a phenomenon of very rare occurrence. He himself has never seen but six cases. In one case there were flaccid paralysis, paresthesiæ, abolition of tendon reflexes, atrophy and quantitative diminution of galvanic irritability—at least in the area of the facialis. A general diagnosis of polyneuritis was therefore in evidence. The symptoms promptly and decisively disappeared under specific treatment. The diagnosis could also be made from coincident phenomena of syphilis and further by exclusion. In alleged polyneuritis the real condition may consist of a poliomyelitis or a nerve root neuritis, and differentiation may be difficult or impossible. An essential isolated and strictly peripheral polyneuritis is now known to be of rare occurrence, probably under all circumstances.

Thorax Phthisicus and Tuberculous Disposition.—Stiller states that the relationship between these two common factors is still obscure despite years of effort to illuminate the relationship. From a very common viewpoint the mechanical impossibility of ventilating the apices of the lungs in the so-called thorax phthisicus is sufficient to explain the clinical phenomenon of pulmonary tuberculosis. From the opposite viewpoint it may be insisted that the so-called phthisical or paralytic thorax is a much less sharply defined entity than has been believed. It is also asserted that there are two separate types of insufficient thorax, in one of which there is involved chiefly a skeletal deformity, while the other is merely due to muscular subdevelopment or insufficiency. The two, of course, have more or less tendency to coexist in the same subject, but subjects with either type of thorax are not necessarily candidates for consumption. Stiller regards it as impracticable to distinguish between the two forms. The dualist would perhaps treat the thorax with contracted apex by division of the first rib and the paralytic thorax by muscular exercises, but in neither case does such special therapeutics appear to modify greatly the pathogenic substratum which really underlies both forms of thoracic anomaly.

Deutsche medizinische Wochenschrift.

January 11 and 18, 1912

Abdominal Injuries.—Riedel concludes a serial article with many practical aphorisms, including the following: The most certain sign of a visceral injury is rigidity of the muscles, which is the result of effusion of blood or escape of intestinal contents. The earlier this rigidity sets in the greater the escape of fluids. Only in rare instances is rigidity absent. When to rigidity are joined a rapid, small pulse, pallor, sunken face, and vomiting the seat of the hemorrhage is the liver, spleen, pancreas, or mesenteric vessels, and operation is urgently indicated. After rupture of the stomach rigidity sets in more rapidly than after intestinal rupture because in the former there is little or no tendency for the rupture to close spontaneously; however, even in minimal rupture of the intestine we cannot feel assured of any actual closure of the wound. It takes at least six hours for escaped intestinal germs to begin to proliferate in the peritoneal cavity. Hence, doubtless, delayed peritonitis often originates from minute ruptures. In any rupture of the canal we should operate within this six-hour period whenever possible. We have always to make allowance for the delayed effects of lacerations in the mesentery, serosa and muscularis, submucous effusion, etc.; these include gangrene of the intestine, fecal abscess, kinking or stricture of the gut. When the nutrition of a portion of peritoneum has been impaired through contusion or injury in general it loses its ability to absorb. An effusion of blood may then suppurate from diapedesis. The resulting abscesses contain no fecal matter. In rupture of the liver hemorrhage is best arrested by suturing the omentum into it. The spleen, however, must be extirpated outright for rupture. The kidney, on the contrary, should be treated conservatively unless hemorrhage quickly threatens life. Slight abdominal injuries not involving a visceral lesion are followed by tympanites in a few hours. Such injuries may lead to severe symptoms, such as vomiting, small pulse, and sunken face—in other words, shock may be present. Conversely, in severe visceral lesions shock need not be present.

Fatal Cachexia Without a Gross Anatomical Substratum.—Rindfleisch reports a case in which autopsy failed to reveal any trace of tuberculosis, cancer, or Addison's disease, although clinically one or the other of these affections should have been present. There were chronic intestinal gastritis corresponding to the achylia gastrica found clinically and intestinal hepatitis with cirrhosis, but, severe as these finds were, they could not explain the notable cachexia which had been present. Some emaciation is readily intelligible, but not the high degree of this case nor the deep brown pigmentation such as often accompanies extreme cachetic states. There was neither diabetes nor amyloidosis. Tuberculosis was readily excluded, likewise carcinoma, but by no means readily, for there was absence of gastric acidity. The exclusion was made chiefly by constant absence of blood in the stools. Addison's disease then seemed to be the only possibility, but there was no pigmentation of the mucosæ. To physical exploration the liver seemed normal in size and consistence. In the present state of our knowledge some autointoxication is absolutely necessary to account for the pigmentation. Cases like the author's have doubtless been described before, notably by Grawitz, and the author chooses to term the affection "Grawitz's cachexia" for the time being, until it can be better comprehended.

Nature of Fever.—Aronsohn takes exception to a recent discussion of this subject by Rolly (noted at the time in the MEDICAL RECORD). He wrote a monograph on the subject in 1906, and as a result of whatever may have since been added to our knowledge concludes that fever is due not to the action of an ordinary toxin, but to that of an anaphylatoxin. Fever is ordinarily a salutary process, but may become the converse if defensive substances fail to be produced. The seat of fever is chiefly the muscles, not the liver. Rolly had evidently overlooked the author's work on "ferments and fever," in which he showed that the proteolytic muscle enzyme had its power trebled in fever, while the proteolytic enzyme of the liver had its activity correspondingly diminished. Further in neurogenic or puncture hyperthemia the increased oxidation of protein agrees with that resulting from infectious fever.

The City Asylum Poisoning Cases (Berlin).—Strassmann publishes the first routine article on this episode, earlier reports having appeared as medical news items or letters to the various journals. Up to December 30 the probable diagnosis was ptomaine poisoning from sausage, or more accurately botulism, a form recognizable from the presence of a specific bacillus. As time passed, however, it was found that the latter could not be detected anywhere and that the antiserum employed in treating such cases was inert. The next possibility was wood alcohol poisoning. It was by no means unlikely that the derelict victims of the poisoning had drunk cheap spirits adulterated with this poison, and the examination of the optic nerve and eyeball for the characteristic changes induced by the latter is still in progress. Clinically there were none of the ocular symptoms which accompany methylism, but aside from these the symptoms would be even better accounted for by the latter than by botulism. Beyond this conclusion data do not go. If methylism should be the final diagnosis our conception of the pathogenicity of this substance must be widened and otherwise modified. Methylism as a type of wholesale poisoning seems unknown in Germany, although it has occurred in parts of Russia, Hungary, and other Continental localities.

Serodiagnosis of Cancer.—Pinkuss sums up recent developments in this field as follows: The antitrypsin reaction is clinical rather than specific in character, although in one case cited it behaved like a specific, and a diagnosis of cancer was made in a patient whose only symptom was sciatica. Since there was nothing else which could have given rise to the increased antitrypsin content of the blood a diagnosis of cancer was made, and the sciatica was found to be due to an osteoblastic carcinoma, which in turn doubtless represented a metastasis from some internally situated primary growth. The antitrypsin reaction has a decided positive or negative value after a cancer has been extirpated, for its appearance then not only shows that a relapse has occurred but that a secondary operation must at once be performed. Other recent efforts in serodiagnosis of cancer, while discussed freely in the text, are not deemed worthy of mention in the author's summary.

Wassermann Reaction and Plumbism.—Hilgermann denies that a positive Wassermann is obtainable in subjects with lead poisoning. He has tested thirty-four cases of the latter—acute, subacute, or chronic—for the reaction, and his results have been practically negative. He believes that the Wassermann when properly made is truly specific for syphilis, and that its occurrence in other affections is the result of employing various modifications of the original technique. It is admitted, however, that modifications may be useful negatively in excluding the possibility of syphilis.

Treatment of Insidious Diphtheria Intoxication.—A. Lingel characterizes as the latter the vomiting and psychic disturbances which may occur in the wake of an attack of diphtheria. To counteract this intoxication he recommends the intraspinal injection of antidiphtheritic serum.—*Deutsches Archiv für klinische Medizin*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

FAMILY HISTORY.

THE examiners in the field will more fully understand the importance of securing accurate family histories if they possess some knowledge of the ideas entertained at the home offices on this subject. It would not be strange if many examiners were laboring under hazy impressions when there is some difference of opinion even among medical directors as to the precise bearing of family records upon the selection of risks, some regarding the family history as highly important while others prefer to be guided mainly by the personal history and physical condition of the applicant. On the whole, as will be seen later on, there can be little doubt as to the advantage gained from the consideration of the average length of life of the ancestors and collaterals and of any decided mortality among them from certain diseases, and it is, therefore, a safe plan to regard both the family and the individual traits.

Undoubtedly many individuals defeat their baneful inheritance through the subjugation of their desires and passions for excesses of all kinds, by living in a favorable environment and following a suitable vocation. If all men could and would observe these and similar wise precautions in a thorough and conscientious way the question of family history might be largely disregarded, but as long as the uncertainties of fortune, environment, and domestic relations continue, the majority of even those anxious to escape their tainted inheritances will find themselves more or less prevented from leading appropriate lives. On the other hand, some men who have not lived prudently do reach advanced age though their families have been almost annihilated by some disease; the survival under these circumstances may be attributed to a reversionary inheritance from some vigorous and robust ancestor.

Tuberculosis plays the chief rôle in the transmission of the tendency to disease, but even in these cases precautionary measures when open to contagion, favorable surroundings, freedom from exposure, a healthy occupation, and strict temperance will greatly modify the danger of contraction of the disease. Volumes of statistics in regard to the relation between family history and the contraction of consumption have appeared. Those compiled by Dr. Marsh (article read at the sixth annual meeting of the Association of Medical Directors) will clearly illustrate the question at issue. Dr. Marsh gives an estimate of the liability to consumption based upon an analysis of 1994 deaths of persons with a tainted record and 2706 cases with an untainted record. With the consumptive mortality among the non-tainted class as a basis, the proportion was increased 30 per cent. in the tainted class. There were only a few cases in which both parents had been consumptive and in these the experience had not been particularly unfavorable, probably on account of the fact that the wife or husband contracted the disease in many instances while nursing the other; the same result was shown when a parent and a brother or sister had died. The proportion of consumption was greatest when two or more brothers or sisters had died. The table of cases with tainted record showed a larger amount of consumption in both those above and below the average weight, but there were twice as many consumptive deaths in those below as in those above the average. Dr. Marsh's diagrams indicate that a good weight overbalances a tainted family history to a marked degree. It may be added that these estimates may fall short of the mark because they consider only those dying from consumption, while it is generally conceded that there is a greater tendency to die from other diseases as well as from consumption among those who have that taint in their family record.

Another class is composed of those who acquire consumption, though no tendency to the trouble is indicated by the family history. It must be remembered, however, that some persons wilfully misrepresent the causes of death, and others have no accurate knowledge or give the causes as they understand them from the family traditions, the real cause of death having been consumption but gradually changed by members of the family to some less dreaded disease.

Childbirth is frequently offered as a cause of death. It has been found from the records that the death of the mother from childbirth has as unfavorable an influence upon the longevity of her children as when the death is said to have been consumption. The best explanation of this is that the mother was really a victim to tuberculosis with the consequent inability to go through the ordeal of labor. This is so well understood by the medical staffs at the home offices that they will usually regard childbirth in the same light as tuberculosis in such cases, whenever the risk is a doubtful one otherwise.

It is common to find that families in which the members lived to good ages bring forth individuals possessing a high degree of vital elasticity and increased resistance to disease which no amount of personal care can give them. On the other hand, poorly bred men yield to some disease, not so much because their ancestors died from that particular trouble as that they inherit a weak power of resistance and a low vitality through which they succumb readily when exposed to the bacilli of tuberculosis, or are attacked by some other disease. A study of death claims shows that a large number of men with tainted family record do not die from the diseases they were expected to inherit from their parents or grandparents, but that many of them die, nevertheless, at a more or less immature age. Consumption, cancer, Bright's, cardiac disease, apoplexy, epilepsy, insanity, diabetes and the alcohol or drug habit are disorders which carry off these descendants, and which occur as interchangeable inheritances. So it is that a family record showing a poor longevity affects the decision at the home office in doubtful cases such as those with an impaired personal history or with weight outside the normal limits and may afford sufficient justification for rejection or for the issuance of an endowment policy in which the contract terminates at a certain age.

The family history has been discussed as far as space allows in order that examiners will fully realize the importance of a searching inquiry into the causes of death. The following suggestions are offered:

1. In eliciting the family record always question the applicant carefully and *specifically* as to whether there was any suspicion of tuberculosis,

insanity, epilepsy, paralysis, or cancer in any member of his family, and the ages at which each one of them died. This inquiry should only extend far enough to include grandparents, parents, brothers and sisters, as this will provide sufficient data for all practical purposes.

2. The statement that parents, brothers or sisters have died of "old age," "exposure," "childbirth," "change of life," "don't know," and similar ambiguous causes of death so often given to gloss over the real troubles should only be accepted in the few cases where the applicant is really ignorant of the nature of the diseases and the exact ages of his near relatives at the time of their death. In such instances the examiner should explain this fact explicitly.

3. A special effort should be made to ascertain the true cause of death when the applicant is under the standard weight or there is a personal history of hemoptysis or pulmonary troubles. If it is admitted in these cases that one or more members of the family died from pneumonia, childbirth, or some chronic ailment, the direct and specific question should be asked as to whether there was any suspicion of tuberculosis in the illness. Even then some doubt will remain occasionally and may be cleared up by drawing out further details concerning the condition previous to death, *i.e.*, whether there were gradual wasting away and other symptoms of consumption.

Moreover, negative as well as affirmative answers should be indicated in the medical report to show that these specific questions have been asked and in this way obviate the necessity of correspondence from the home office to clear up the doubtful points.

4. Half brothers and sisters should always be included in the family record and such relationship stated.

The Social Engineer in the Field of Public Health.—In an address delivered at the fifth annual meeting of the Association of Life Insurance Presidents, held in New York December 13 and 14, 1911, Dr. Luther H. Gulick said that Society at present lacks an efficient organization that would help to apply the vast medical knowledge gained in the last few decades to actual human needs. Our equipment for securing facts, as illustrated by the numerous research institutions, are more adequate than that for securing action upon these facts. Health and longevity of the people can be increased by obtaining pure water, effective sewage systems, pure air in dwellings and workshops, reasonable hours of work, protection against infection, etc., etc. Adequate vital statistics should be obtained in all States. The various organizations now existing, such as the Federal laboratories, State health departments, etc., need strengthening rather than increase in number. They must be provided with sufficient finances, must work for better public support, and must have more freedom from political influences.

Public opinion on health matters is to a great degree individualistic, while the needs are nowadays primarily social. People think deeply and spend much money for health, but it is mainly for individual and not social health, and the individual suffers from the sins and omissions of society in this matter.

The Sage Foundation during the past few years has studied the broad question of child hygiene, and its activities are illustrative of needed activities in other similar fields. In 1907 there were 111 cities having medical inspection of school children; there are now 411. The number of Fourth of July casualties steadily increased until 1909, when it reached 5307. Since then it has gradually decreased because of well directed agitation, and last year it was reduced to 1603 for the entire country. Playgrounds have been introduced in a great many cities. The Sage Foundation, in working toward these results, cooperated in developing a National Playground Association, which now coordinates and stimulates various public activities in this field. An effectual press service has been organized, city officials have been enlisted in the movement, model plans have been prepared and persons interested in the matter have been kept in touch with the work. Thus any money now given for the purpose of establishing playgrounds is much more effective than many times a similar amount in the past.

Dr. Gulick proposed the following principles of action for securing results in other similar fields of social welfare. Existing channels for reaching a desired community should be utilized, that is, newspapers, magazines, clubs, medical societies, lecturers, school officials, etc. Scientific information, well formulated, should be furnished. Subjects should be promoted only when they are ripe; they must occupy the stage, if not the very center of it. A subject must be pushed agressively when once taken up by the public, for public attention cannot be retained very long. Only a few subjects should be promoted at a time. Public attention must be concentrated to be effective, for distraction is deadly. Only such schemes as are reasonably promising of success should be pushed, for failure hurts every other similar project.

These principles are stated not because they are exhaustive, but because the social work can be no more left to chance for success than any other work. The "social engineer" needs a knowledge of individual and mass psychology; he must be a man of science as much as a modern structural engineer.

A body for promoting social health must be philanthropic and absolutely non-commercial. The public must feel that there are no ulterior motives back of its teachings. The Association of Life Insurance Presidents should promote public health in some such way as proposed above.

Increase of Death Rate Above the Age of Forty.—Since 1880 the American death rate per 1,000 population has been reduced about 25 per cent. This is due chiefly to the spread of knowledge as to the cause and the means of prevention of tuberculosis, typhoid fever, diphtheria, smallpox, etc.; to the increase of interest in sanitation and to the adoption of more healthful living habits by the people. Yet the death rate above the age of forty has increased heavily, the causes of mortality above this age being chiefly the common chronic affections of non-communicable type. These affections are for the most part diseases of the kidneys, of the heart and of the blood-vessels; against them no such war has been waged as against diseases of infancy and childhood and the infectious diseases of the adult. Yet these diseases of advanced age are likewise to a great degree preventable or postponable. It would seem as if the time was ripe for a campaign of education in reference to the causes of mortality above the age of forty similar to the campaigns against infant mortality and against common infections. Certainly, a life saved from Bright's disease or from heart disease is as valuable as a life saved from typhoid fever or from an accident.—*The Human Factor*, December, 1911.

State Invalidity Insurance in Germany.—According to official statistics just published there were at the end of 1910 in the German empire 23,188 *krankenkassen* with 13,069,375 members. In the year 1910, 5,107,089 cases of sickness occurred among the members, amounting to 104,708,105 days of illness. The income amounted to $94,875,000 and the ordinary disbursements to $87,512,500. Among the latter are included the costs of illness, $80,000,000.—*Journal Am. Med. Assn.*

Book Reviews.

A Mother's Guide. A Manual for the Guidance of Mothers and Nurses. By Francis Tweedie, M.D., Alumnus Bellevue Hospital, New York; Fellow of the New York Academy of Medicine; Assistant Physician to the Babies' Hospital Dispensary, New York. Price $1.00. New York: James T. Dougherty.

Mothers, and prospective mothers, often ask a physician to recommend them some small book dealing with the nursing and feeding of infants, and with the management of some of the more common ailments incident to child life. The present volume is well adapted for this purpose; it is written in clear and simple language, and the directions are complete and safe. Most books of this kind tell a great deal too much, and are often as dangerous as they are useful; this little work is an agreeable exception.

Aids to Histology. By Alexander Goodall, M.D., F.R.C.P. Edin., Lecturer on Physiology, School of Medicine of the Royal Colleges; Examiner in Physiology to the Royal College of Physicians, Edinburgh. Price 2/6. London: Baillière, Tindall & Cox, 1912.
